the typhoid bacillus. There is a marked tendency for typhus serum to develop heterologous antibodies as in my case which developed such for *Treponema pallida*, for *B. typhosus*, for *B. proteus* X 19 and for *Staphylococcus aureus*. Doubtless many other heterologous antibodies unsuspected and untested for were also so developed and such if tested for during the course of the fever would have been successfully demonstrated. This peculiar reaction of typhus serum to a range of organisms deserves fuller investigation.

6. *Intraperitoneal guinea-pig inoculation.*—On the 31st October (being the 14th day of the disease) and when the patient's fever was at its highest, four ounces of his blood were injected intraperitoneally into a male guinea-pig weighing 510 grammes. After losing 70 grammes in the first three days the guinea-pig remained well at a constant weight of 460 grammes. There was no fever and no testicular swelling.

After the chimpanzee and monkey, the guinea-pig is the most susceptible experimental animal to the typhus virus. In the guinea-pig after a 10 days' incubation a non-fatal febrile illness of some 10 days' duration develops, characterized by wasting, effusion into the tunica vaginalis with ear rash and swelling. In Indian tick typhus such inoculations have failed whilst in European, Mexican, and Rocky Mountain fever the guinea-pig is reported commonly to contract the infection.

My thanks are due to Dr. S. P. Gupta, Lecturer in Pathology, for the interest he took in the agglutination findings which are entirely his own work. Also to the Central Research Institute, Kasauli, who kindly undertook their parallel agglutination observations from the same serum, taken on the same dates.

APPENDIX

The first two cases of tick typhus recognized at King George's Medical College and in India, both by Major Megaw, I.M.S., are outlined below:

Case 1.—(From the I. M. G. of January 1917 and of October 1921.) A healthy European of 42 years, on

1st July, 1916, whilst staying at Bhowali about two miles from Sat Tal, found a tick firmly fastened to his neck. The tick was not identified but it was considered that it might be *Rhipicephalus sanguineus* or *Hyalomma aegyptium*. On the 21st July a twelve days' fever started. The symptoms were malaise and orbital headache, with some pain in the back muscles which caused disturbed sleep for two or three nights. On the fifth day a diffuse macular erythema was noticed all over the body including the palms, soles and face. In two further days the eruption was maximal, the colour changed to brownish-red whilst about the eighth day the spots had a distinct tendency to become petechial. The eruption faded rapidly with the fall of the temperature but a brown staining at the site of the spots was visible for about five weeks afterwards. The spots were roughly circular in shape and varied from three to seven millimetres in diameter; at first they faded on pressure. The patient was not toxic and rose from his bed the day on which the fever reached normal. Widal reactions to *B. typhosus* and *paratyphosus* on the ninth and eleventh days were negative. Blood culture on the 9th day was negative, and subcutaneous inoculation of one-half c.cm. of blood into a monkey on the eleventh day gave negative results. The total leucocytes on the eleventh day were 15,400 and an average count was polymorphonuclears 68 per cent, small mononuclears 25 per cent, large mononuclears 6 per cent and eosinophiles 1 per cent. The abundant rash, the negative Widal and definite leucocytosis excluded the typhoid group.

Case 2.—(From King George's Hospital Medical Case Sheets of October 1917.) G. L., a Hindu of 38 years, was admitted on 30th October, 1917, into King George's Hospital under Major Megaw—complaining of (1) fever, (2) joint pains (both for 10 days) and (3) constipation (2 days).

Patient was a forest officer, who had been working in the Hamirpur District of the Jhansi Division at Kunehta Forest seven miles from Maudaka since July. He resided in a bungalow half a mile from the village. The area was a damp jungle place, with many cattle but little cultivation. He did not recognize the presence of ticks but was much troubled from the bites of many insects before the fever began. On 22nd October, the fever started with a slight chill and continued in an increasing degree every day, the temperature in the evening becoming high and decreasing in the morning. Pain was present in all the joints. On 30th October, the day of admission, the patient was very weak, so that he was unable to give a very accurate history. For the past two days he suffered from severe headache, mental depression and constipation. He had slight toxæmia. The whole body except the palms, soles of the feet and the face was covered with a spotty rash each spot of which was rose-red in colour, fading on pressure, and about the size of a mustard grain. The spots do not vary in size. Its intensity was most marked on the extensor surfaces of the extremities but widely diffused over the trunk. The alimentary, circulatory, respiratory and urinary systems were normal. The total white count was 14,000 and the differential showed polymorphonuclears 73 per cent, lymphocytes 20 per cent and large mononuclears 7 per cent. The Widal against typhoid and paratyphoids A and B was negative in all dilutions.

On 2nd November the rash was noted as subsiding and becoming pigmented. On 11th November, being the 21st day of the fever, the temperature reached normal for the first time and remained thereat throughout the patient's convalescence.

SUMMARY

1. Three cases of tick typhus have been recognized at King George's Medical College, Lucknow. The first two cases (summarized in the appendix) were also the first described in India, and formed the

foundations of our present knowledge of this type of typhus infection.

2. Historically, the first step towards this knowledge was McKechnie's observation in 1913 that the endemic continued fever of Bhim Tal was not a typhoid group fever but was a subvirulent non-epidemic typhus infection, unassociated with the usual typhus epidemiological conditions of poverty, famine, overcrowding, dirt and lice.

3. The second step was Megaw's observation in 1916 that a case of Bhim Tal fever apparently followed a tick bite, together with his explanation that the sporadic distribution of tick typhus was due to the exposure of individuals, living a camp life in the open jungle, to bites from ticks; which had themselves become infected from jungle rodents.

4. The third step was the recognition that heterologous serological reactions are not unusual in typhus serum which observation was so clearly proved in the third case of tick typhus diagnosed at King George's Hospital in 1934.

5. The clinical features of this third case are fully described and leave no room for doubt as to the correct clinical diagnosis.

6. The serological reactions of the third case showed (1) a Wassermann reaction which was positive (+ + ±) during the continuation of the fever and became negative when the temperature reached normal, (2) a Widal reaction positive to *B. typhosus* in a dilution of 1/833, (3) a Wilson-Weil-Felix reaction positive to *B. proteus* X 19 (1/2,500), (4) a high opsonic index to *Staphylococcus aureus* (4.6), and (5) some increase in the total white leucocyte count, all of which fell to approximately normal within a month or two of convalescence. Such reactions in this case were not due to syphilis or to typhoid infection, for both diseases were definitely excluded both clinically and also by a complete series of laboratory tests.

7. But positive Wassermann reactions, positive agglutination reactions to *B. typhosus* and to *B. proteus* X 19 have been frequently reported in individual cases and groups of typhus infection. In louse typhus, a positive Wassermann during the fever is commonly present. A positive Widal to the typhoid group has often obscured a real diagnosis of typhus. Whilst the positive agglutination of *B. proteus* X 19 frequently found in typhus serum formerly led to the belief that typhus infection might be due to a parasitic phase of *B. proteus*.

8. Thus the deduction is reached that typhus toxin has the peculiar property of stimulating intensely but non-specifically varied antibody producing (hæmopoietic) tissues. Further, typhus serum may show individual or multiple non-specific serological reactions, which are ordinarily considered individually specific to, and diagnostic of, their respective infections.

9. Apart from Bhim Tal and Sat Tal, a second endemic area probably exists near the Kunehta Forest in the Hamirpur District of the Jhansi Division, for the second and third cases both contracted their infection in this same area. The second case was a forest officer, who had been camping in this area for three months previous to his attack. The third case was an American missionary who had also been camping for a month previous to the onset of his fever within some seven miles of the second case's original camp. Both cases developed a similar atoxic mild fever lasting in each case for 21 days, with a similar diffuse roseolar-macular body and limb rash and being contracted in both cases at the end of the hot weather in October. This possible endemic area is being further investigated.

8. There was also evidence of the development of some slight agglutination against *B. para A*, *B. para B*, *B. proteus K*, *B. proteus 2*, *B. coli communis* and *B. coli communior* for a few days during the patient's infection. No agglutinins were noted against

(2) In the reticulum of the spleen and lymph nodes, where they form a great network through which the blood or lymph slowly percolates. These cells are provided with long filaments, which intermesh and form the reticulum or splenic pulp.

(3) Along the lining of specialized venous sinuses in the spleen, bone marrow and liver. In the liver the cells are called Kupffer cells and line the liver sinusoids.

(4) Within the splenic network, caught, as it were, in the meshes, where they are termed splenic cells. These cells are intimately bound up in the production of the mobile element of the system, which is resident in the blood and there helps to swell the number of white cells under the name of 'monocytes'.

Several suggestions have been made as to the origin and inter-relationship of these cells, and although there is some agreement in the suggested theories, by no means all the authors conform to any generalized plan. Figure 1, however, gives briefly the essentials, namely, that the reticulo-endothelial system in the spleen, etc., form the monocyte by division, and that the free histiocyte of inflammatory lesions comes from both fixed histiocytes and monocytes which have migrated to the lesion from the blood. The fibrocyte or cell of the fibrous tissue is formed from these free and fixed histiocytes.

From this description it can readily be seen that the cardinal feature of the structure of the reticulo-endothelial system lies in its diffuseness; it permeates the whole body, and is ready, in fact, to deal with any foreign matter which may present itself.

On the other hand, its chief physiological characteristic is ingestion, or phagocytosis, and this action, combined with intra-cellular digestion, lies at the bottom of any function which may be attributed to the system. In many ways the amoeba likens itself to a reticulo-endothelial cell, for if, in its passage across the bottom of a stagnant pond, the amoeba encounters a smaller animal or other particle of food, it surrounds it with a pseudopodium, and allows it to pass through the limiting cell membrane. Once inside it is digested and disappears into the general cytoplasm. The difference, however, between a reticulo-endothelial cell and an amoeba is that the latter ingests only food substances, whereas the reticulo-endothelial cell ingests any particulate matter which is presented to it. The system is, then, a scavenging system ready to clear the blood and tissues of any debris or noxious material which might hinder the function of the cells.

In view of this phenomenon of ingestion, it is not surprising that several important phagocytic functions have been attributed to the system. When a tadpole becomes a frog it loses its tail, and this is brought about by the phagocytes actively ingesting them, and liberating the products of digestion into the blood to be dealt with elsewhere. Similarly, phagocytosis takes place around the ends of any growing long bone of the skeleton, for since the end of the bone is wider than the adult shaft, it is clear that some bone must have been absorbed, because it was all originally produced from the same epiphyseal cartilage. Another instance of phagocytosis is the removal of the distal portion of a severed nerve fibre. As the axis cylinder breaks up the local reticulo-endothelial cells help the neurilemma cells in removing the debris and myelin of the sheath. They thus leave a pathway clear down which the new cylinder may grow. As stated above, the system may phagocytose colloidal dye—in fact, any

matter which is not in solution and is floating about in the blood and tissues is liable to be absorbed by these scavenger cells. If a tissue is damaged in any way, then it will be cleared of debris and dead tissue by the reticulo-endothelial cells. On the property of dye absorption depends the process of 'blocking'. The process is used to eliminate as far as possible the effects of the reticulo-endothelial function, and depends upon the fact that so much dye may be absorbed into the cells that they become quite useless for further processes, and this measure, combined with splenectomy, is largely used in determining what part the reticulo-endothelial system plays in any particular process.

A process which has now been attributed to the reticulo-endothelial system is that of the breakdown of hæmoglobin to form the green pigment of the bile—bilirubin.

For many years it has been known that bilirubin was one of the products of hæmoglobin breakdown, and since the bile was excreted by the bile duct it was legitimately supposed that the liver cell was the site of this transformation. The only contradictory evidence to this theory, moreover, was the fact that if blood was forced into the tissue spaces, as in a bruise or black eye, a pigment was formed during the breakdown of hæmoglobin, which resembled bilirubin very closely. This theory had for its support the classic experiments of Minkowski. He took some geese and, cutting out their livers, injected a solution of hæmoglobin into their circulation, and thereon, finding that no bilirubin was produced, concluded that the site of its production, and therefore of the breakdown of hæmoglobin, was the liver cell.

However, it was soon found that bilirubin was present in human blood serum, which, of course, would be impossible if the liver were the only site of its formation, and this stimulated McNee in 1913 to repeat Minkowski's experiments. At first he obtained the same results, but when he used dogs instead of geese, he found that he could find bilirubin in the blood, even after complete liver removal. But, unfortunately, this did not satisfy everybody, for it was suggested that McNee's bilirubin was reabsorbed from the alimentary tract, and it was not until Mann in 1924 removed both liver and alimentary tract *in toto* and still was able to obtain the pigment in the blood that the extrahepatic formation of bilirubin was validated.

The available evidence then began to point to the reticulo-endothelial system as the site of hæmoglobin breakdown. It was possible, of course, that the breakdown occurred in the blood, but that was eliminated by perfusing an ordinary 'heart-lung preparation' with hæmolyzed blood and failing to obtain bilirubin.

Rich found that he was able to grow reticulo-endothelial cells in culture tubes, and that these cells broke up the hæmoglobin that he presented to them. It was also found that if the reticulo-endothelial system was 'blocked', bilirubin could not be formed in the circulation.

But the most conclusive evidence of all is that, if the bilirubin content of the artery and vein supplying an organ are compared by the van den Bergh reaction, it is found that in the vein leaving an organ rich in reticulo-endothelial cells there is a marked bilirubin increase, and further, the reticulo-endothelial cells can be shown histo-chemically to contain the bilirubin in crystalline form, before it is liberated into the blood stream.

It may be seen why Minkowski's experiments on the goose were so misleading, because in these animals the liver contains not only liver cells, but also all the reticulo-endothelial system as well. Further, it is now clear why a bruise should break down to form bilirubin in the tissue spaces, for there lie the histiocytes, ready to break up any extravasated hæmoglobin

and repair any damaged tissues, which its presence may have caused.

The next interesting function of the reticulo-endothelial system is the part it plays in fighting infection by a micro-organism.

The body defends itself from invasion by micro-organisms with three barriers:—

1. The intact skin, and mucous membranes. This is a very important barrier, but the reticulo-endothelial system plays no part in its maintenance.

2. The tissue fluids. These consist of the blood and lymph, and in them are the various antibodies of the body.

3. The reticulo-endothelial cells.

These last two defence mechanisms are responsible for the phenomenon of immunity, which consists in the host becoming more sensitive to the presence of the invader, and being able to eliminate him the more easily. The body of the host does this in two ways:—

(a) By producing antibodies in the tissue fluids which kill the organism and neutralize its irritating toxins; and

(b) By increasing the power of the reticulo-endothelial phagocytosis to a remarkable extent. Although these mechanisms work well in the ordinary host, the production of immunity is the sensitization and speeding up of these bodily processes.

When the organism has passed barrier one, the intact skin, it may be eliminated in one of two situations: either in the tissue spaces, where an abscess is probably formed, or in the blood stream and reticulo-endothelial system elsewhere.

In local infections the reticulo-endothelial system can actually be watched going about its business, when an infected web of a frog's foot is placed under the microscope. Vessels are seen to dilate, and white cells of the blood migrate fast to the site of the infection. However, at first polymorphonuclear cells only, which are not members of the reticulo-endothelial system, attack the organism. The latter, when many are dead and pus is beginning to form, the histiocytes and monocytes enter the battle and phagocytose not only the remaining unkilld organisms, but also all the dead polymorphs and debris of the damaged tissue. Their job is, therefore, to make way for a reconstruction, which is undertaken by the fibrocyte and is in the nature of a formation of fibrous tissue to bind the sides of the cavity, so formed, together. The whole process of local inflammation may also be watched in exudates in the peritoneal cavity, and if the reticulo-endothelial cells have been vitally stained beforehand the part played by the system can easily be assessed to be one of reconstruction.

In general infections or infections which have reached the blood stream the part played by the reticulo-endothelial system is mainly determined by 'blockage' methods. For instance, it was found that in animals previously 'blocked' and having undergone splenectomy infections became both more virulent and more rapidly fatal. This is true of bacteria, spirochaetes, or even viruses. In similar animals it was found possible to infect them with a species of organism to which the normal animal was naturally resistant, and it seems that natural resistance is an enormous power of phagocytosis, which the animal exhibits towards the particular organism, for instance the frog to the pneumococcus and the hen to bacillus anthrax.

Further, if an immunized animal was taken, it was found that by splenectomy and 'blockage', immunity could be broken, and the animal became as susceptible to infection as a normal animal. Outside the evidence of 'blockage' is still the fact that bacteria can be demonstrated in the reticulo-endothelial cells in the process of being digested during an infection, and these

cells are found to be able to absorb remarkable numbers in the immunized animal.

Some say that the tissue fluids alone are responsible for immunity, but this theory may be disposed of on the grounds that if an immunized animal is taken and its whole blood volume changed with that of another non-immunized animal, immunity still persists, showing that it is cellular in nature and only helped by the humoral mechanisms in the tissue fluids.

In specific infections, such as syphilis or tuberculosis, the part played by the reticulo-endothelial system in the untreated disease is mainly one of phagocytosis of the causative organisms, and the reticulo-endothelial reaction is more predominant by far than in the ordinary pyogenic infections, where the polymorphonuclear response is the rule. But if the disease is treated, it seems that the system plays a large part in the accentuation of the drug that is given. For instance, when arsenical compounds, such as neosalvarsan, are used in the treatment of syphilis, it appears that they are rapidly absorbed by the reticulo-endothelial system, and then slowly liberated again when the organism comes within reach. This opinion is held because if neosalvarsan is used against the organism in culture tubes, very little effect is produced, and further, that if the system is 'blocked' with dye, the neosalvarsan remains in the blood, and is quickly eliminated by the liver and kidneys before producing the required results. In fact, for the drug to be effective in killing the spirochaete the defence mechanisms of the body must be available. The sanocrysin given for tuberculosis acts in a similar way, but since this compound is colloidal in nature it probably stimulates the reticulo-endothelial cells to greater phagocytic action, for small amounts of any colloid stimulate reticulo-endothelial tissue. The mode of action of sanocrysin is particularly interesting because it may be possible to find drugs which can stimulate reticulo-endothelial cells in a great many more clinical conditions, and modern therapeutics is tending more and more towards stimulating reticulo-endothelial tissue.

The problem concerning the site of production of barrier two of the antibodies in the blood is much discussed. The obvious theory is that they are produced by barrier three of the reticulo-endothelial cells, but the evidence for this is of the flimsiest. Since the bacteria are taken up by the reticulo-endothelial cells it might be supposed that from the protein of their carcasses, so to speak, antibodies would be produced, but the results of 'blocking' the reticulo-endothelial system are most disappointing, and it cannot be said definitely that this is so. The other piece of evidence in favour of this theory is the fact that if the reticulo-endothelial cells are grown in jelly they can be made to form antibodies, but the results of any culture experiments must be very carefully accepted because the surface of an agar slope is scarcely homologous with the complicated environment within the human body.

However, modern belief tends towards the theory that the reticulo-endothelial system is both responsible for the cellular defence, or third barrier of the body, and the humoral, or second barrier of the body, which comprises the tissue fluids and the antibodies within them.

Metehrihion has recently made some wonderful experiments to show that this phenomenon of immunity, which is equivalent to sensitization of the body, may be synonymous with sensitization of the central nervous system. He has taken an earthworm and, finding that it will develop an immunity to cholera vibrio, has destroyed its third segmental ganglion, when he found that it was then impossible to produce immunity. If, however, he destroyed any other ganglion, the production of immunity was still possible, and thus he associates the production of immunity with the third segmental ganglion in the worm.

Further, he has tied a ligature round the centre of a worm so that only the nerve cord remains, but the blood supply was cut off, thus leaving the two halves united solely by the cord. Then, on immunizing the back half of the worm, he found that immunity also developed in the front half, and concluded that the cord had been the means of its transference. But the most conclusive evidence of all his experiments is that on the rabbit. He immunized this animal to cholera by a series of injections of dead vibrio, which he associated in the animal's mind with the ringing of a bell after the style of the conditioned reflexes of Pavlov, and when immunity was at its height, he waited three weeks and allowed it to fall to a normal level. He then commenced to ring the bell alone at regular intervals, and found, to his delight, that the immunity rose again to a high level, thus showing immunity to be a sensitization of the central nervous system, which could be called out at any time to a proper stimulus. The inference must be drawn, then, that the reticulo-endothelial system, although so diffuse, is probably controlled by a nervous or hormonal mechanism.

Lastly, there is the function of controlling the growth of neoplasms, and, more particularly, cancers.

Since cancer is a new formation of tissue, it might be thought obvious that the reticulo-endothelial system could be responsible for its control and possible removal; but that is by no means the case, and the theory of the reticulo-endothelial control is now advanced tentatively on but small grounds.

The spleen seems to be the chief source of tumour resistance, because malignant growths rarely set up secondaries there, and Beuda suggests that this organ gives out a positive substance, for she finds that when the spleen is removed, tumours become more easily transplanted and grow more quickly.

Further, it has been discovered that if tumour cells are planted into an animal along with the splenic cells, no growth is formed, and that if a mouse is 'blocked' with dye, it becomes more susceptible to a tumour to which it was before insusceptible.

Other evidence is largely circumstantial. For instance, tarring the skin is known to produce new growths, and it is also known to damage the local reticulo-endothelial cells considerably. Also the emanation of radium is known to produce tumours, as are also x-rays, and both these emanations are known to weaken the reticulo-endothelial system considerably. The aim, therefore, in therapeutics with these two radiations must rather be to give very small doses to stimulate the reticulo-endothelial cells than to give larger doses in order to kill the tumour cells and damage irreparably the reticulo-endothelial system. The clinical evidence, however, is still lacking, for no records have as yet been made as to the state of the reticulo-endothelial system in cancer patients, and, indeed, only a few tests as to the state of the reticulo-endothelial system efficiency exist, and until this is done the part played by the system in the cure of cancer must remain *sub judice*.

Conclusion

Pathologically, then, the reticulo-endothelial system plays a large part in the control of disease, and the tendency of modern therapeutics should be towards improvement in its efficiency rather than towards eliminating the invader by more direct methods. Prophylaxis means a good reticulo-endothelial mechanism, and lucky is he who has such a system, for if, for any reason, it should fail, it would be bad for him.

Physiologically, however, the system is the example *par excellence* of the motto which is engraved upon the heart of all good physiologists, 'Function Determines Structure'.

The Necessity for the Standardization of the Treatment of Bacilluria

By A. M. CRANCE, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CIV, 26th January, 1935, p. 285)

CONSIDERING the fact that modern urology has in general made great strides forward during the past two decades, there is still a wide discrepancy within the profession regarding the management of urinary infections, particularly those infections which are due to the *colon bacillus* group. This discrepancy should actually not exist. Its remedy is obtainable only by effecting some definite standardization in the management of bacilluria in general. My purpose in this paper, therefore, is to summarize briefly the reasons why such a therapeutic standardization is possible as well as advisable.

Needless to say, it has apparently not yet been learned that there is no urinary antiseptic which eliminates the *colon bacillus* from the urinary tract. Drugs, therefore, are of little value in treating this infection.

It must furthermore be borne in mind that urinary infections due to *B. coli* rarely ever disappear spontaneously. It was only a few years ago that one of the great urologists said that, in his opinion, when a patient develops *colon bacillus* infection in the kidneys he is bound to go to his grave with the kidneys still infected. To-day, since advances in the management of bacilluria have become so obvious, this statement is decidedly out of order. Approximately 80 per cent of *colon bacillus* infections in the urinary tract can be completely eliminated by conscientious, practical methods of therapy.

In 1924 a small series of cases was reported in which complete recovery occurred by the use of autogenous vaccine, given in rather large doses at five-day intervals over a period of from eight to twelve weeks. Many physicians have little use for vaccines, I am not an exception to this belief. However, so far as *B. coli* infections are concerned, it is perhaps one of the most valuable aids to date.

Continuing to work out more effective measures, because it was obvious that not every case would respond to one form of treatment alone, I began to wonder why nearly all these cases showed infection in one or both kidneys. In fact, all cases were thoroughly studied on the cystoscopic table, and in more than 90 per cent the infection was found to originate above the bladder. Why should this be true? Why also did so many of these cases give histories of chronic constipation, or in fact some intestinal upset, such as diarrhoea, prior to the appearance of cystitis symptoms? The reason is, I believe, that the *colon bacillus*, whose natural habitat is in the colon, is by virtue of its increase in numbers politely invited to seek a new residence and, by gaining entrance to the lymphatic system, finds its way to the kidney, where it is known to become a pathogenic, pus-producing organism. With this theory firmly in mind, the treatment then became more of a matter of treating the colon, the focus of infection. It is quite evident that if the number of *B. coli* in the intestinal tract can be reduced to somewhere near normal, the organisms will cease leaving it to go elsewhere.

Three methods may be used, and in fact all three methods should be used, in attacking the problem of correcting the focus: first, by daily enemas; second, by changing the intestinal flora each two weeks with a sudden change in diet—i.e., two weeks high protein, two weeks high fat, and two weeks high carbohydrate; third, by the daily use of a good acidophilus preparation, preferably not in milk. These, together with the aforementioned autogenous vaccine, constitute four important measures, which I have termed the 'four-point treatment'. As reported in 1923, it gave 80 per cent satisfactory results, and this percentage has

remained the same. This method of treatment was used long before the various types of the colon group were differentiated.

TYPES OF BACILLURIA

Bacillus coli constitute approximately 80 per cent of all urinary infections, excluding of course the gonococcus. To-day it is definitely known that two distinctly separate types of *B. coli* exist; namely, the *Escherichia* and the *aerogenes* varieties. These constitute nearly all the cases of bacilluria. Others, which occur far less frequently, are *Pseudomonas* (*B. pyocyaneus*) and *B. proteus*.

Of chief concern in this paper is the management of the *B. coli* group. First of all, it must be borne in mind that this discussion does not deal with cases presenting surgical complications, such as perinephric abscess or surgical pyonephrosis but rather it is to deal with the type of case in which treatment is considered medical in character.

IMPORTANCE OF DIAGNOSIS

Diagnosis is of primary importance. Samples of urine for culture should always be collected by catheter in the female, and in the male by careful cleansing of the meatus prior to voiding in a sterile container. Cultures will show practically all types of bacillus infections and the coccus group such as staphylococci and streptococci, tubercle bacilli excepted. When *B. coli* is found, usually in pure culture, the laboratory should go further and subculture the specimen to determine which type is present. A very simple method may be used for determining this. *Aerogenes* produces gas within forty-eight hours in saccharose, whereas *Escherichia* does not. Both types form gas in lactose. It is very important, as I will try to point out, to know which type is present before any outline of treatment is attempted. As already stated, I have obtained approximately 80 per cent successful results in the treatment of *B. coli* infections during the past ten years by the so-called four-point treatment. This method yields results in the *aerogenes* type practically as well as it does in the *Escherichia* variety.

Clark, formerly of the Mayo Clinic, and also Helmholtz have shown in several recent reports that about four out of five patients presenting infection with *Escherichia coli* will completely recover by the ketogenic diet treatment. During the past two years, I have been able to obtain approximately the same percentage of recoveries in this type, using the ketogenic regimen. The principle of the ketogenic treatment probably needs little explanation, excepting that the work of Fuller of England has shown that a specific agent (1-B-hydroxybutyric acid) is produced in a ketone urine and that this agent destroys the colon organism. A recent editorial in *J. A. M. A.* also reviewed in an interesting manner the action of this specific agent. The diet also strives to yield a urine with a pH somewhere below 5.1. Colon bacilli are destroyed in an acidity of from 5.1 to 4.6. (Normal urine averages approximately from 6.8 to 5.8.) Clark also obtained satisfactory results in seven out of twenty-one cases presenting the *aerogenes* type. In ten cases of the *aerogenes* type that I treated, the ketogenic regimen failed in each instance. Therefore, with one worker showing only one out of three patients recovered, and another showing no recoveries, why should the ketogenic diet be considered as a method of choice in treating the *aerogenes* type?

This is exactly where the standardization of definite therapy enters the picture. Since the *Escherichia* type of *B. coli* responds to both the ketogenic regimen and the four-point treatment with approximately equally satisfactory results, one has the choice of either. The ketogenic diet is much the quicker method if it produces the result, from ten to twenty days usually being sufficient. Against the ketogenic diet is the fact that hospitalization is necessary, or at least the patient

must go to the hospital for meals, if the utmost co-operation is to be obtained. On the other hand, if the ketogenic treatment fails in this type, the other treatment may be resorted to. Conversely, patients failing to recover with the four-point treatment may completely recover under the ketogenic regimen. Generally speaking, therefore, in infections with *Escherichia coli* the ketogenic diet, when possible to carry out conveniently, is the method of choice. The other method can always be resorted to if necessary.

For reasons previously stated, the ketogenic diet, in my opinion, is not at all indicated in the *aerogenes* type of *Bacillus coli* infections. The percentage of successful results has been too low to warrant the advisability of submitting patients to the expense of hospitalization or dietary measures. The *aerogenes* type decidedly calls for the four-point treatment. My results with this type have been entirely satisfactory, and in fact I feel that the *aerogenes* type definitely contraindicates the use of the ketogenic regimen. It has occasionally been necessary to repeat the course of treatment; persistence, until complete recovery, is essential to its success.

Pseudomonas (*B. pyocyaneus*) infections respond exceptionally well to the ketogenic diet, as do the majority of the remaining types of organisms found less frequently in bacillurias. In the *pseudomonas* infections, Clark was able to obtain sterile urines from thirteen out of fourteen patients treated.

AUTHOR'S FOUR-POINT TREATMENT

1. Autogenous vaccine, made up 1,000 million per cubic centimetre, is given intragluteally at five-day intervals, beginning with 0.5 c.c. and increasing each subsequent dose by 0.5 c.c. until the dosage of 2 c.c. is reached. Usually a course of twelve injections is given.

2. Daily enemas are given. The soapsuds enema is used, the size being increased up to 2 to 2½ quarts. This portion of the treatment helps to eliminate an excess of colon bacilli from the intestinal tract, which is the focus of infection.

3. Previous work has shown that *Bacillus acidophilus* definitely aids in changing the intestinal flora and also that it aids the intestinal tract in its function of elimination. It is prescribed in liquid culture form because in milk it would interfere with the change in diet mentioned in the fourth item.

4. Two weeks of high protein diet, two weeks of high fat diet and two weeks of high carbohydrate are given for the purpose of changing the intestinal flora, which in turn decreases the number of colon bacilli in the colon. It is occasionally necessary to continue on with this diet if the urine still shows positive cultures at the end of the first six weeks.

Summary

The first remark should deal with the importance of bacilluria. Too often is this type of case 'passed up' as something inconsequential, to be treated only with urinary sedatives or the supposedly antiseptic preparations. Too often does the physician believe, because the symptoms subside under these remedies, that he has cured his patient. *B. coli* infections especially may subside sufficiently to warrant this belief. Actually, however, the infection goes on, and sooner or later a 'flare up' occurs, at which time it will erroneously be termed a 'recurrence'. It is not a recurrence in the true sense but rather an acute exacerbation, simply because the case was not carried along to complete recovery at the time of the previous treatment. A cure depends on three things—no more, no less. These are freedom from symptoms, a urine free from pus and an entire absence of bacilli on culture. The culture must be sterile.

Conclusions

The following conclusions are directed entirely to the standardization of the treatment of bacilluria.

1. The physician should have courage enough to discontinue the use of oral medication with urinary antiseptics. It has previously been proved that they will not yield a sterile culture of the urine.

2. *Bacillus coli* cultures must be subcultured, since the treatment depends on the type, whether *aerogenes* or *Escherichia*.

3. *Escherichia* infections heal very satisfactorily under the ketogenic diet in fully 80 per cent of the cases. When this fails, the four-point treatment is indicated. It is well to remember that the two treatments yield equally good results but that the ketogenic treatment is usually somewhat quicker in effecting a cure.

4. In the *aerogenes* type of *B. coli*, the four-point treatment appears to be by far the better method of attack. It will require from eight to twelve weeks of persistent effort, on the part both of the physician and of the patient.

5. *Pseudomonas*, and other less common types of bacilluria, apparently respond best to the ketogenic treatment.

6. The stubbornness of *B. coli* infections in general being realized, a complete cystoscopic study of each case, including differential function, elimination of ureteral strictures, and the like, should be made. Pathologic changes that will interfere with the treatment should be known in the beginning. It would seem more advisable for the physician to make such a study before treatment is instituted rather than to find out later why the treatment failed.

Dosage Above the Pharmacopœial Maximum

By ARTHUR F. HURST, M.D. (Oxon.), F.R.C.P. (Lond.)
(Abstracted from the *Lancet*, 22nd December, 1934, p. 1379)

THE dosage given in the B. P. represents the average dose given to adult patients. Experience shows that under certain conditions very much larger doses of certain drugs can be given with advantage. In some instances, as in the case of atropine, this is due to the great variations in individual susceptibility, the same therapeutic effect being obtained in a very susceptible individual with a dose which may be only a half or a quarter of the dose required for a patient who is unusually resistant to the action of the drug. In other cases recent therapeutical investigations have led to the discovery that a more powerful and sometimes quite different effect can be obtained with a dose much greater than that given in the B. P.; the larger dose has then generally to be administered with special precautions. In such cases it would only be safe to alter the official dosage if it were possible at the same time to add a note as to the method of administration.

IRON IN ANÆMIA

In spite of the large amount of work which has been done in recent years on the treatment of anæmia and the admirable accounts published by Dr. L. J. Witts on the indications and dosage of iron, it is surprising to find how little care is often taken in deciding whether a case is one which will benefit with iron or with liver, proprietary preparations combining the two together being very popular. The dosage of iron is generally quite insufficient, complicated organic preparations are too often ordered instead of the simple inorganic preparations, which are also the most effective, and iron injections have not yet passed into the oblivion they deserve.

Anæmia as a cause of symptoms is far more common than is generally recognized, and many middle-aged women with chronic ill-health, which is often ascribed to the menopause, are really suffering from

an easily curable anæmia. The vast majority of cases, including those which follow hæmorrhage, respond with great rapidity to efficient treatment with iron. When I first came to Guy's in 1901 the popular mist. ferri arsenicalis contained five grains of iron and ammonium citrate with five minims of liquor arsenicalis. When I was Dr. Beddard's clerk in the out-patient department he told me to double the dose of iron and halve that of arsenic. Later I increased the iron to fifteen grains and then to twenty grains, and Dr. Witts has shown us that we should increase it still further to thirty grains. It is unsafe to give much larger doses, as one patient of mine almost died from acute iron encephalopathy following the administration of forty grains four times a day for three weeks. We now know that arsenic is useless, and that iron given by injection is quite inert; the popular and expensive Fraise's ferruginous serum may have some effect on the mind, but it has none on the blood. When thirty grains of iron and ammonium citrate are given three times a day, the hæmoglobin generally increases by about one per cent a day, and still more rapidly if the anæmia is severe; for example, a youth of twenty with splenic anæmia who came in with 14 per cent hæmoglobin was prepared for operation by giving him this dose of iron; his hæmoglobin percentage rose to 76 in 45 days.

Though there is a popular notion that iron causes indigestion and leads to constipation there are very few people who cannot take thirty grains of iron and ammonium citrate in half an ounce of water three times a day after meals as long as is necessary without unpleasant results. The anæmia, which is always present after hæmorrhage from an ulcer and which delays healing if left untreated, rapidly responds to this treatment, and so far from irritating the gastric mucous membrane the iron appears to have a directly favourable action on the ulcer and the associated gastritis. In a recent case the hæmoglobin percentage, which, two months after a hæmorrhage, was only 48 rose to 87 in 25 days.

The anæmia in carcinoma of the stomach and colon often improves very quickly, and no case should undergo operation with less than 80 per cent hæmoglobin. Only if the hæmoglobin is very low is it necessary to hasten matters by one or more preliminary transfusions.

Liver and stomach are quite useless in all anæmias except Addison's (pernicious) anæmia and some closely allied megalocytic anæmias, such as that of sprue, and it should be reserved for such cases.

HYDROGEN PEROXIDE AND HYDROCHLORIC ACID IN ACHLORHYDRIA

Achlorhydria is a common sequel of chronic gastritis and is present in about 15 per cent of all patients suffering from abdominal symptoms as well as in about 4 per cent of perfectly healthy young adults. In about 75 per cent of cases the power of secreting acid can be restored by dieting, removal of septic foci from the mouth and throat, and lavage of the stomach when fasting in the morning with dilute hydrogen peroxide (half an ounce to the pint). The hydrogen peroxide acts as a mild antiseptic and dislodges the mucus adhering to the mucous membrane. The treatment is repeated daily until the washings are clear. In many cases a fortnight is enough to restore the secretory activity of the stomach, but in some cases the patient has to continue with the treatment himself for several weeks.

Since I began using hydrogen peroxide lavage for gastritis eight years ago only about a quarter of the patients to whom I should formerly have given hydrochloric acid now require this drug. It should never be used except as a temporary measure until a second test-meal after a course of lavage has shown that achlorhydria is still present, as it is infinitely more satisfactory for a patient to provide his own acid than to have to take it from a bottle. When

the gastritis is so severe that all the acid-secreting cells are destroyed, and when the achlorhydria is due to an inborn error of secretion, as it may be in the rare cases of constitutional and familial achylia gastrica, hydrochloric acid should be given.

When one drachm of dilute hydrochloric acid is mixed with five ounces of water it is only slightly weaker than natural gastric juice. Thus diluted, with the addition of the juice and pulp of an orange and sugar, it makes quite a pleasant beverage, which should be taken before breakfast and with lunch and dinner for the rest of the patient's life. The usual dose of dilute hydrochloric acid is quite inadequate. This was first clearly shown by some experiments made in cases of Addison's anaemia, a condition which is almost invariably associated with incurable achlorhydria, by Dr. Maurice Shaw when my house physician in 1922. He found that one drachm of dilute hydrochloric acid sipped during the hour following a test-meal was rarely sufficient to neutralize the alkaline contents of the stomach, so that no free acid appeared. Occasionally one and a half drachms produced a normal curve and two drachms a hyperchlorhydric curve, but more frequently two drachms were required to produce a normal curve of acidity. In rare instances even two drachms did not lead to the appearance of free acid.

HEXAMINE AS A BILIARY ANTISEPTIC

It has been known for many years that hexamine is excreted by the bile, but Dr. F. A. Knott was the first to prove definitely that it acts as a biliary antiseptic in spite of the bile being alkaline, although in the urinary tract it is inactive unless formalin is set free by the acid urine. Pure bile obtained through a duodenal tube has no antiseptic action, but if large doses of hexamine are given, the bile, which can be shown to contain unaltered hexamine, is strongly antiseptic, and any bacteria which are present in it before the treatment begin to disappear. Formerly the maximum dose of hexamine which could be given with safety was limited by the supposed necessity of keeping the urine acid. But hexamine is just as efficient a biliary antiseptic when sufficient alkali is given to make the urine permanently alkaline; under such conditions no formalin is set free, and enormous doses can be administered without causing any bladder irritation. A mixture containing sixty grains each of sodium bicarbonate and sodium citrate in two ounces of water is given after breakfast, after tea, and last thing at night after drinking a glass of milk or water. The reaction of the urine is tested every time it is passed; as soon as it is found that the urine is constantly alkaline, if necessary after the dose of the alkalis has been increased, a hundred grains of hexamine is added to the mixture, so that three hundred grains are taken a day. The treatment can be continued for periods of six weeks. The hexamine sterilizes the bile-ducts and gall-bladder, and, when combined with non-surgical biliary drainage by means of Epsom salts, it results in the cure of most cases of cholecystitis. This treatment should be given for a week or two before and after operations on the gall-bladder and bile-ducts in order to guard against septic complications. In cases of severe infective cholangitis with jaundice, high temperature and rigors, it has sometimes appeared to save the life of the patient.

Hexamine is excreted into the cerebrospinal fluid and has been found by experiment to prevent the development of poliomyelitis in monkeys inoculated with emulsion of the spinal cord from fatal cases. I think, therefore, that large doses are worth giving in the manner I have just described to contacts in poliomyelitis epidemics, and possibly also during the acute stages of encephalitis and for the cerebral complications of ear and sinus disease.

I should like to suggest that in the next edition of the B. P. explanatory notes should occasionally be

given under the head of dosage. Thus in the 1932 edition the dose of hexamine is given as ten to thirty grains. But five to fifteen grains is the correct dose when it is used as a urinary antiseptic, and fifty to a hundred grains as a biliary antiseptic. For the former acid sodium phosphate or similar drug must be given to keep the urine acid, and for the latter alkalis must be given to keep it alkaline. The higher pharmacopoeial doses—fifteen to thirty grains—are too small for biliary antiseptics and too large for urinary antiseptics, as if given alone and especially if given with acid sodium phosphate they would be very liable to cause severe hæmorrhagic cystitis.

ATROPINE IN THE TREATMENT OF ULCER

There is no doubt that the presence of free acid in the stomach is an essential factor in the development of gastric, duodenal, and anastomotic ulcers, and that such ulcers tend especially to develop in individuals with the hypersthenic gastric constitution in which more than the average quantity of acid is secreted. Successful treatment largely depends upon choosing a diet which calls forth as little secretion as possible and has a high neutralizing power. Alkalis are given to neutralize still more of the free acid, and olive oil and atropine to inhibit its secretion. It is a familiar fact that some people are much more susceptible to the action of atropine than others. Its influence on salivary secretion is approximately parallel to its influence on gastric secretion. In order, therefore, to obtain a maximal effect on the stomach the dose should be increased until the largest quantity is given which does not make the mouth unpleasantly dry. I give 1/200th grain of atropine sulphate dissolved in a drachm of water before three of the feeds and a double dose last thing before going to sleep, as it is particularly important to inhibit the continuous secretion of acid during the night, when there is no food in the stomach which can partially neutralize it. Both doses are then increased by ten minims of the mixture—i.e., 1/1200th grain—every day until the patient complains of unpleasant dryness of the mouth or paralysis of accommodation. After reducing the doses by ten minims they are continued throughout the period of treatment. As the atropine dries the mouth it may be assumed to dry the stomach, and actual tests have shown how effective it is in reducing the quantity of free acid present. It is impossible to guess beforehand what will be the adequate dose in any given individual. Occasionally a patient cannot take more than the initial 1/200th grain three times a day and 1/100th grain at night; the majority can take about 1/100th grain, whilst occasionally as much as 1/40th grain is found to be the correct dose for the day and 1/40th plus 1/200th for the night. It is important to increase the dose in this way, as I believe that 1/200th grain would be without any effect on the last patient though sufficient for the first; in other words, 1/200th grain in one individual is equivalent to 1/40th grain in another.

MORPHIA FOR INCURABLE PAIN

In spite of all the modern advances in therapeutics we must still often rely upon morphia for the alleviation of pain. Inoperable cancer is not necessarily very painful, but when it involves the spine and in many cases of carcinoma of the liver and of the pelvic organs the pain is excessively severe. By the fearless use of morphia it is always possible to keep a patient with this terrible disease comparatively happy and completely free from pain. There is obviously no need to fear the development of a drug habit in a dying patient, but most doctors are curiously averse to giving the huge doses which may be required in such cases. I do not think that the various substitutes for morphia have any special advantage. The dose should be found by experiment which, when given at sufficiently frequent intervals, keeps the patient completely free from pain. As the tissues quickly develop

the power of destroying increasing quantities of morphia so that only a small proportion is left to exert its analgesic effect, the dose has to be steadily increased in order to remain adequate. The dose required during the last week of life in a patient who survives for an unusually long period may be huge—as much as fifty grains a day, but it should be remembered that this is really equivalent to about one grain a day at the onset of treatment, most of the morphia being destroyed in the liver and other organs. Many patients with secondary cancer of the liver and spine live for many weeks, and even many months, and I am inclined to think that the morphia often delays death—its one disadvantage, though this is more a disadvantage to the unhappy relatives than to the sleeping patient. For a proper dose is one which keeps the patient in a continuous state of twilight sleep; the sleep is often dreamless, but when dreams occur they are generally happy ones. The patient is easily roused three or four times a day to take a little nourishment, but he only wakes sufficiently to smile and murmur a few words.

ADRENALINE IN ASTHMA

The pharmacopœial dose of adrenaline is both too large and too small. It is too large for habitual use in ordinary cases of asthma and too small for use in the exceptional cases of status asthmaticus. In spite of recent advances in our knowledge of asthma it is comparatively rare that a patient is given such complete relief that he never has another attack. It is therefore necessary in almost every case to devise some treatment for the asthmatic paroxysm itself.

In the treatment of the asthmatic paroxysm the preponderating activity of the vagal over the sympathetic nerve-supply to the bronchi can be overcome by means of drugs, such as atropine, which paralyse the vagus, or by adrenaline, which stimulates the bronchodilator fibres of the sympathetic. The inhalation of fumes from powders containing stramonium or belladonna, which was formerly the universal method of treatment, had the grave disadvantage of causing chronic bronchitis by irritating the bronchial mucous membrane. This treatment should never be used, as the opposite method of restoring the balance by means of adrenaline has no such disadvantage and is also more promptly and more constantly effective. The patient should be taught to inject the adrenaline himself, as if he does this at the first sign that an attack is developing it will be aborted, and one or two minims will often be sufficient, though five or more would have been required had he had to wait for a doctor or nurse to give the injection at the height of the attack. This small dose gives rise to none of the unpleasant symptoms often caused by larger doses, which sometimes make a patient prefer the asthma to the adrenaline, and as it does not even raise the blood pressure there is no danger of damaging the arteries. Its use has in many cases the further justification of making good a deficiency in the secretion of adrenaline, just as thyroid preparations do in myxœdema. The treatment also reproduces the way in which relief may on rare occasions occur under natural conditions. If an individual during a severe attack of asthma comes under the influence of sudden fear or anger, the two emotions which W. B. Cannon showed stimulate the secretion of adrenaline, the attack immediately ceases, the patient having had an 'autogenous dose' of adrenaline. We may hope that the time will come when asthma will be curable, but until that consummation has been attained, the proper use of adrenaline deprives asthma of most of its terrors, and makes it possible for every asthmatic to live a life of moderate activity. The patient should be provided with a pocket case containing a small bottle of adrenaline, a special small all-glass hypodermic syringe with very fine bore so that minims and half minims can be accurately measured up to a maximum of seven minims, an 'iodine pencil' and a spare needle.

The rare condition of status asthmaticus, in which severe asthma continues uninterruptedly for days or weeks and may end in fatal exhaustion, can always be arrested by the method of continuous adrenaline injection which I first used about ten years ago. The needle is kept in position with a full syringe, and after an initial injection of a dose which is known to cause no unpleasant symptoms, one or more minims are injected every 15, 30, or 60 seconds, according to the patient's reaction, the rate being varied until it is found how frequently the injection can be made without tachycardia or other symptom arising. The injections are continued, if necessary, for even half an hour or more; relief always follows and generally manifests itself by the patient falling into a deep sleep, which may be the first he has had for several days.

Anaphylaxis can also be most efficiently treated by this method of injecting adrenaline, which is far more effective than occasional injections of larger doses. If adrenaline is always at hand when a patient is given serum or other treatment which may cause anaphylactic reaction, the latter should never prove fatal.

The Basal Metabolism of European Women in South India and the Effect of Change of Climate on European and South Indian Women

By ELEANOR D. MASON

(Abstracted from the *Journal of Nutrition*, Vol. VIII, No. 6, 10th December, 1934, p. 695)

MEASUREMENTS on thirty-four European women resident in the city of Madras, which has a mean annual temperature of 82.8°F. and a relative humidity of 72 per cent, showed an average metabolism 7.9, 6.3, and 12.5 per cent below the Harris-Benedict, Dreyer and Aub-DuBois standards, respectively. By the same standards this was 9.0, 9.9 and 4.7 per cent above the average metabolism of Indian women in Madras. The mouth temperature was slightly higher than reported in Western countries and the pulse and blood pressure as low or slightly lower. These three measurements do not differ significantly from those of Indians. The European vital capacity was normal and very much higher than that of Indian women.

Nine European women studied in both temperate and tropical climates showed two types of response to the tropics. One group showed a marked decrease in metabolism, a fairly marked fall in pulse rate and no rise in mouth temperature. The other group showed no change in metabolism, a slight fall in pulse rate and a rise in temperature of from 0.2°F. to 0.7°F. The high correlation found in this small group of subjects between change in metabolism and change in temperature is supported by a high correlation between temperature and metabolism in the series of thirty-four women measured in Madras. The average decrease in metabolism of the group of nine moving to the tropics was 5.1 per cent. Three Indian women measured in two climates showed an increase in metabolism of 4.8 per cent in cold climates. These data suggest that approximately 5 per cent of the low metabolism previously reported for Indian women may be attributed to the effect of tropical climate.

Treatment of Undulant Fever

By J. E. DEBONO, M.D.

(Abstracted from the *Lancet*, 16th February, 1935, p. 374)

THE treatment of undulant fever has always been baffling and disappointing. Although the mortality is relatively low, the protracted course of the infection, together with the monotonous succession of relapses and our therapeutic helplessness, make this disease one of the most trying to the patient and to

his medical attendant. Very many remedies have been suggested ; sera, vaccines, protein shock, chemotherapy, and other less orthodox methods have been experimented with. From time to time enthusiastic reports are published, but despite occasional successes the general impression is that the disease tends to run its course in spite of treatment.

In 1929, while working with Prof. Zammit on the immunization of goats, it occurred to me that the filtrate which was being used as a prophylactic might also have a therapeutic effect. Subsequently it was discovered that melitine had already been suggested and used as a therapeutic agent. No claim to originality is therefore made.

The first results, although definitely encouraging, were somewhat inconstant. This was probably due to the low potency of the original filtrate and to excessive caution in the dosage. In 1931 and 1932 a supply of brucellin was obtained through the kindness of Dr. I. F. Huddleson, and in 1933 a small quantity of the specific nucleoprotein. The results obtained with these and with an eight-week filtrate of *Brucella melitensis* have exceeded all expectations and have encouraged me to the publication of this preliminary note.

In all 105 cases have been treated up to date. Of these 68 were seen during the first pyrexial wave, usually within three or four weeks of the onset. In another 30 the infection had been present for more than two but less than six months, while in the remainder it had assumed a chronic form. The majority were of the moderately severe type common in Malta. There were no malignant cases.

The technique adopted after many experiments was as follows :

An intradermal injection of 0.2 c.cm. was first given, in order to confirm the diagnosis and to gauge the patient's reactivity. The subsequent dosage depended on the local and general reaction to this injection, the stronger the reaction, the weaker the initial dose. As a rule this varied between $\frac{1}{2}$ and $\frac{3}{4}$ c.cm., and was given intramuscularly.

With a sufficient dose the thermal reaction is sharp and immediate. The temperature begins to rise in 6 to 12 hours, reaches a maximum in 12 to 18 hours and is usually down by the next day. In the most favourable cases it drops to considerably below normal. Headache, shivering, and general malaise are frequently observed, but although the temperature may rise above 105°F., it does not persist at this level for more than a few hours and no untoward symptoms have been observed. A second injection of $\frac{1}{2}$ to 1 c.cm. is given in 3 to 4 days according to the severity of the reaction.

In the majority of cases two to three injections are sufficient, a fourth being given to make doubly sure.

At first the injections were only given during the decline of the pyrexial wave, or when the temperature was relatively low. As time went on it was realized that in the acute cases the reaction was relatively mild and did not upset the patient to any extent. The filtrate was therefore used more extensively and without waiting for the temperature to come down.

The results varied with the period of the disease and with the preparation used. During the first pyrexial wave it was possible to obtain a definite abortion of the infection in 58 out of 68 cases. In the majority of these the temperature came down permanently after the third or fourth injection. In 8 five doses were required. In the light of more extended experience it seems probable that the failures were due to insufficient dosage and lack of perseverance.

In chronic cases the effect is not so striking. The reactions tend to be more severe and smaller doses have to be used. This susceptibility is particularly marked in patients who have been treated by ordinary vaccines. It was relatively easy to cut short a pyrexial wave but the fever tended to reappear after a longer or shorter interval. Lately it was found possible to prevent further rises by continuing the injections during the apyrexial period. Of the 37 patients in this group 20 reacted satisfactorily, the fever subsiding in less than a fortnight. In 6 cases the treatment had to be abandoned on account of the severity of the reactions, while in the other 11 the filtrate did not seem to be making any permanent impression on the temperature chart.

In a disease like undulant fever, where the course is so erratic and the duration so indefinite, it is difficult to assess the value of any particular line of treatment. In the present series, however, the results have been so immediate, so true to type, and so relatively constant, that it would be pedantic to attribute them to coincidence in every case.

Similar results have been obtained in America by Huddleson and Howard, who have published a series of 80 cases treated successfully with brucellin. In France melitine and the specific endoprotein have been used extensively, and very good results have been reported by Montel, Melnotte and Masson, Cambessèdes and de Nattan-Larrier, and by Cambessèdes.

It is, of course, too early to claim melitine or brucellin as an infallible specific, and there is still considerable discussion as to its mode of action; but there is enough *prima facie* evidence to justify further investigation and a more extensive trial.

Reviews

THE COMPLETE PEDIATRICIAN. Practical, Diagnostic, Therapeutic, and Preventive Pediatrics, for the use of Medical Students, Internes, General Practitioners, and Pediatricians. By Wilburt C. Davison, M.A., D.Sc., M.D. 1934. Duke University Press, Durham, N.C.

The title page of this remarkable compilation is an adaptation of the title page of the *Compleat Angler* by Izaak Walton, 1653, and the resemblance between the two books does not stop there. It is easy to picture the author as a disciple of the gentle art and he must have had his tongue in his cheek when he chose such an appropriate title. The contents of the book require as much playing and patience as the wildest salmon, but perseverance will always land a good catch.

The book contains a vast collection of facts and data relating to the science of the pediatrician and represents an enormous amount of painstaking and

detailed work. Naturally it emanates from America which country has been the author and finisher of all potted goods. But there are many good canned products and the *Compleat Pediatrician* is a sample of the good class.

The book has been arranged in the same sequence as the physician uses in examining and treating a patient. Chapter I is devoted to signs and symptoms, and the numbers given after each heading refer to chapter II, which is headed diseases, differential diagnosis, and treatment. Here each disease is catalogued from abscess to yellow fever. Chapter III discusses preventive measures and child care, and chapter IV, the administration of fluids and blood to infants. Chapter V is probably the best part of the book and here the author breaks into ordinary prose and the book takes on an almost human touch. The reading matter in this chapter is excellently displayed, clear, full and precise. The directions for the feeding

of normal infants and older children will be of considerable value to the harassed practitioner who can rarely find such a wealth of definite and direct information in any one single book on the subject of diabetes.

Chapter VI is devoted to drugs and prescriptions used in pediatrics and the last chapter, to laboratory methods.

The format of this book is good, the printing clear, and errors of any kind are rare.

The book will be of value to both students and practitioners, especially the latter, but cannot be recommended as a useful book for candidates preparing for examinations. Its place is on the desk as a reference book, which can be relied on as accurate, concise and thoroughly up to date. It does not provide the peaceful atmosphere of the usual textbook and leaves the reader to gasp with astonishment at the industry and perseverance of the author. It fulfils a definite need and many will find its compressed pages a real treasure, albeit a treasure that needs hunting for.

D. M.

RECENT ADVANCES IN NEUROLOGY.—By W. Russell Brain, D.M., F.R.C.P., and E. B. Strauss, D.M., M.R.C.P. Third Edition. 1934. J. and A. Churchill, Limited, London. Pp. xiv plus 442, with 40 illustrations. Price, 15s.

The present edition is a distinct advance on its predecessors. A considerable amount of new matter has been added and in this connection special mention may be made of cerebral angiography, new conceptions of neurotropic viruses—poliomyelitis and acute encephalomyelitis—and nerve complications in infectious diseases. The physiological and clinical interpretations of the symptoms produced by different pathological changes in the brain and nervous system will be of great value to students and medical practitioners. The book consists of 23 chapters, the first 20 chapters deal with the pharmacological and pathological study of cerebrospinal fluid, intracranial circulation and intracranial tumours, various changes produced in the tendon reflexes, vision and pupils, and the postures of the body. The last three chapters deal with the injection treatment of sciatica, ketogenic treatment of epilepsy, and x-ray therapy for intracranial tumours.

The book is very well written and will be greatly appreciated by students of neurology for the up-to-date information regarding the recent advances in this difficult but important subject.

R. N. C.

HIGH BLOOD PRESSURE.—By J. F. Halls Dally, M.A., M.D. (Cantab.), M.R.C.P. (Lond.). Third Edition. 1934. William Heinemann (Medical Books), Limited, London. Pp. xxii plus 281. Illustrated. Price, 15s.

THE reception accorded to this useful handbook on blood pressure has led to the publication of the third edition and the author has thus had the opportunity of bringing the work thoroughly up to date. The present volume has been re-written and a considerable amount of relevant matter and fresh illustrations have been added.

Arterial hypertension, as symptomatic of various underlying causes, is the theme of this book. The causative factors, the clinical manifestations, and the study of control of high arterial pressure have been presented from the view-point of practical medicine. The author has covered the whole ground in a very matter-of-fact, concise, and lucid manner, and, in spite of the vast literature reviewed, there is no overloading. The list of references appended at the end of the book is of great help to those who desire further information.

The book can be confidently recommended as an accurate and practical guide to the senior students, and the general practitioner on this important subject. It makes easy and pleasant reading.

R. N. C.

RESEARCHES ON TROPICAL TYPHUS. A STUDY OF THE BACTERIOLOGY, SEROLOGY AND EPIDEMIOLOGY OF THE DISEASE.—By Ludwik Anigstein, M.D., Ph.D. Studies from the Institute for Medical Research, Federated Malay States, No. 22, Kuala Lumpur. 1933. Pp. 184; illustrated.

A GREAT deal of confusion exists regarding the typhus group of fevers. Besides the classical typhus exanthematicus various typhus-like fevers have been described which differ in their clinical and pathological features in different parts of the world. It is therefore very refreshing to read this present monograph on tropical typhus by Dr. Anigstein from the Institute for Medical Research, Kuala Lumpur. Tropical typhus in the Malay States was first described by Fletcher and Lesslar in 1925; they distinguished two types—the rural and the urban type. During the author's period of investigation there were 237 notified cases, 170 of which were of the rural type and agglutinated XK, while the remaining cases belonged to the urban type and agglutinated X 19. The author was successful in conveying the disease to several arthropods, guinea-pigs, rats and rabbits, and found Rickettsia-like organisms in the congested tunica vaginalis of these animals. From the various strains of organism isolated from human and animal cases Rickettsia-like bodies, spindle-shaped organisms, coccobacilli and proteus forms were obtained. Dr. Anigstein is of opinion that the virus of typhus represents the parasitic stage of proteus X.

The question of the probable vector of the disease is still undetermined. *Trombicula deliensis* is suspected, but the author failed to infect a volunteer with emulsion of crushed mites. Body lice are not the usual vectors though they could be infected by allowing them to feed on patients or by rectal inoculation. A mixed prophylactic vaccine was used with promising results as a prophylactic measure in an endemic palm-oil estate. The book will be read with interest by all those who are interested in the subject.

R. N. C.

WHAT OF THE CHILD?—By Dr. Andrew Kefalas, M.A., M.B., Ch.B. 1934. William Heinemann (Medical Books), Limited, London. Pp. xvi plus 187. Price, 5s.

MANY are the errors into which parents may fall in the upbringing of their children. Dr. Kefalas as a medical psychologist has frequently met with and overcome the results of these errors in management, and the outcome of his practical experience is this small and simple book.

It deals mainly with psychological problems in the upbringing of the pre-school and school child, and of the boy or girl during puberty and adolescence; it is thus wider in scope than most books of similar type. Advice is given on the choice of books and of a school, on the nature of the religious and sex instruction which should be given at different ages, and on the varying relationships between parents and children as the latter become more and more individual and independent. The advice is definitely personal in outlook and expression, but it is never extremist. The author is 'fairly temperate, and reasonable', and the book should prove helpful to many parents and teachers who wish to guide their children to a sane and happy adjustment to life under our present-day civilization.

J. M. O.

A HANDBOOK OF OPHTHALMOLOGY.—By H. Neame, F.R.C.S., and F. A. Williamson-Noble, F.R.C.S. Second Edition. 1935. J. and A. Churchill, Limited, London. Pp. xiv plus 339, with 12 plates, containing 46 coloured illustrations and 147 text-figures. Price, 12s. 6d.

THERE are so many excellent books on ophthalmology written in the English language that one is

surprised at the appearance of yet another, but as this is the second edition of the handbook this alone is proof of its popularity and usefulness.

The book has been brought up to date by the addition of modern methods in the treatment of retinal detachment by electro-coagulation, recent work in the aetiology of glaucoma, the treatment of ptosis by Greeve's operation, the increased uses of tuberculin, the use of T.A.B. vaccine in protein shock therapy and treatment by ultra-violet radiation. There is also a chapter devoted to tropical ophthalmology which is unfortunately disappointing, and will be of little practical use to the medical man working in India.

More space should have been devoted to and emphasis made on diseases which are very prevalent in India. For example superficial punctate keratitis, glaucoma and the various complications of syphilis. These are so often not diagnosed in the early stages. On the other hand descriptions have been given of diseases which are rarely seen.

Beri-beri is a disease which is practically unknown in India but is often confused with epidemic dropsy which is common in Bengal and one of the great causes of primary glaucoma. Likewise pellagra is rarely seen. The commonest ocular complications of malaria are retinal hæmorrhages of all kinds and produced in the great majority of cases by the accompanying anaemia. 'Malarial amblyopia' and to a lesser extent quinine amblyopia are very uncommon occurrences in spite of the large amount of malaria that occurs in India.

The ocular complications of dysentery are also rare.

The only eye operations mentioned in the chapter on tropical ophthalmology are the treatment of cataract by Smith's operation of intra-capsular extraction and the 'three needles operation' for the treatment of anterior staphylomata. Undoubtedly the best treatment for the removal of cataract in the large proportion of cases is by the intra-capsular method and it is not more difficult or dangerous in experienced hands, but the so-called Smith operation should only be attempted in the case of senile cataracts which are hypermature and which are not possible to remove by the forceps or Barraquer methods. In the large teaching centres in India the Smith operation is not popular as it is considered unsafe and dangerous and with present up-to-date methods vitreous loss should be almost entirely eliminated. The author does not point out the importance of facial akinesia as a routine in all cases, as it eliminates all squeezing and to a great extent the importance of the assistant. The method is simple and can be learned very quickly even by the inexperienced operator. It is truly one of the greatest advances in modern operative ophthalmology. It should not be necessary to give general anaesthesia in the operation for the removal of cataract, and no case should ever have both cataracts removed at the same time.

The book is well supplied with black and white and coloured illustrations and with the exception of the chapter on tropical ophthalmology is excellent and we recommend it for students who wish to study ophthalmology.

E. O'G. K.

AIDS TO SURGERY.—By Cecil A. Joll, M.S. (Lond.), M.D., F.R.C.S. (Eng.), and R. C. B. Ledlie, M.B., B.S. (Lond.), F.R.C.S. (Eng.). Sixth Edition. 1935. Baillière, Tindall and Cox, London. Pp. x plus 612, with 44 figures. Price, 7s. 6d.

THE 'Students' Aids Series' is sufficiently well known to need an introduction. The present (sixth) edition is a decided improvement on its predecessors. The chief danger of a synopsis of this type is that it is apt to encourage the pernicious habit of cramming. The surgical dresser, who has done his clinical work well, will find, in this book, a satisfactory outline of the subject.

Hilton's method of opening a deep abscess has not been quite accurately described. He advised the use of a grooved probe or director and a blunt instrument like a pair of dressing forceps. In the treatment of tetanus, avertin possesses many advantages over inhalation anaesthesia and magnesium sulphate. Foundin has practically supplanted antimony tartrate in the treatment of bilharziasis. In case of the tropical or solitary abscess of the liver, repeated aspirations combined with emetine injections are usually successful. The paragraph on elephantiasis is inadequate. Elephantiasis nostra or non-filarial elephantiasis has been practically ignored. We should have much preferred to see melanoma, included under carcinoma.

Owing to rapid advances in our knowledge, surgery has assumed a bulk which it is difficult to assimilate. It is therefore desirable that textbooks of surgery should deal mainly with fundamental facts and practical points, discarding alternative archaic methods of diagnosis and treatment. Sayer's method of treatment of a fractured clavicle is a case in point: it hardly deserves a paragraph to itself. Greater space might have been usefully devoted to important subjects like Böhler's method of non-padded plaster casts and Kirschner's wire traction. A noteworthy feature of the present edition consists of its excellent illustrations, for which great credit is due to the editors. The index appears to be adequate and the volume is of a suitably small size.

P. N. R.

SIMPLE INSTRUCTIONS FOR DIABETIC PATIENTS.

—By Dorothy C. Hare, M.D., M.R.C.P. Second Edition. 1935. Published by H. K. Lewis and Company, Limited, London. Pp. 22. Price, 1s.

A REVIEW of the first edition of this little book appeared in this *Journal* about two years ago. The present edition contains, like its predecessor, much useful information of a somewhat broad and general nature and as such may prove to be of value to diabetic patients undergoing treatment, as well as to nurses having to deal with such cases.

J. P. B.

DIABETES MELLITUS AND OBESITY.—By G. G. Duncan, M.D., C.M. (McG.). 1935. Published by Henry Kimpton, London. Pp. xii plus 215. Illustrated. Price, 12s. 6d.

THIS book has been written from a practical point of view, and in its simple and clear style will make a special appeal to medical students and general practitioners, most of whom have very little time to go in for the theoretical and controversial matters in connection with the disease, but require a good working knowledge of the disease and its various complications.

One useful section of the book deals with obesity, especially in relation to the part it plays in the aetiology of diabetes.

We are of the opinion that both the medical student and the general practitioner will find the book of much help in dealing with cases of diabetes in a practical and methodical way.

J. P. B.

A BRIEF OUTLINE OF THE MODERN TREATMENT OF FRACTURES.—By H. Waldo Spiers, A.B., M.D. 1935. Baillière, Tindall and Cox, London. Pp. ix plus 129, with 109 figures. Price, 8s.

DR. SPIERS states in his preface that he has written this brief outline of the modern treatment of fractures merely to illustrate the fundamentals of bone surgery, because modern textbooks are so filled with illustrations and operative technique that the average student is frequently at a loss to know what it is all about.

He has certainly succeeded in his object and has put before the student, albeit extremely briefly, the fundamentals of bone surgery. He has been careful to

warn the young practitioner not to put his faith too much in metal, but to use other and absorbable material when it is necessary to perform an open reduction and fix the ends of the fragments.

Dr. Spiers recommends that metal plates should only be used when it is impossible to keep the fragments in alignment by any other means. Truly a sound surgical dictum. Many other sound principles are brought to the notice of the reader but on the whole the book is too short and too scanty of detail to stand alone.

However, if the student when preparing for his examinations will read this book in conjunction with his textbook and digest its contents it will have served its purpose and for this it can be recommended.

H. E. M.

THE CHAIN OF LIFE.—By Guyon Richards. 1934. Published by John Balo Sons and Danielsson Limited, London. Pp. xiii plus 215. Price, 6s.

THIS interesting book of 215 pages deserves to be read not only by medical men, be they allopaths or homeopaths, but also by scientists, philosophers, spiritualists and laymen. The matter contained in the book relates to the subject of ætheric waves and their relation to disease. It is well presented and grips the reader in a manner similar to that of Edgar Wallace's stories. It is impossible to summarize the twenty-two chapters of the book or to comment on them individually. For purposes of this review it is enough to state that in the book the view is expressed that the whole universe is pervaded by ætheric waves or 'wireless' waves and every animal, plant, and non-living matter sends out and receives, even though situated at great distances from one another, ætheric waves. These waves operate on them differently according to their nature. So far as man is concerned the waves influence the state of his body and mind. In health man sends out one kind of wave and in disease another kind. By recording the nature of the waves sent out by the body in some suitable receiving set it is possible not only to determine whether a person is healthy or diseased but also to state what the nature of the illness is. All that one has to do is to study the ætheric waves emanating from a sick person by putting him in an electric circuit as for obtaining an electrocardiogram and then after having noted the deflection in a galvanometer to refer to the diagnostic table provided. It is interesting to learn that the reading for cancer is 80,441, for syphilis 88,037, for rheumatism 65,061, for malaria 38,150 and so on. It is not only diseases that can be detected in this way but also certain mental states. The figure for a suspicious person is 12,717, for a despondent person 85,530, for a forgetful person 47,653, for a restless person 77,130 and so on. The researches conducted by the author also indicate that there is only one disease and that differences in manifestations noticed are merely due to differences in the stage of the disease. With regard to treatment, man being body, soul, spirit and ætheric waves, it is important to treat all these factors. Drugs, diet and the knife are not enough to cure the case. The environment, the psyche and the ætheric waves that influence man should also be considered and properly tackled. This can only be done by first determining the ætheric waves of drugs, food-stuffs and endocrines, studying their relation to the diseased state and then giving such of them as would influence the case favourably. In the book a detailed list of the substances to be used is also provided. By way of comment we wish to add that after reading the book one certainly feels that the future of mankind is extremely bright and that the state will not have to worry itself with any public health or medical problems. It will not build hospitals nor train doctors, for treating the sick, it will not employ a huge public health staff for preventing and controlling the spread of infection. All that it will do will be to

instal a large number of electrical apparatus, similar to the one recommended by the author, at different parts of the state so that people may go to them and by putting a penny in the slot, by observing the number that is indicated by the dial, and by pressing the specified button obtain a packet of medicine which will not only cure them of the disease that they suffer from but also establish balance and harmony in the ætheric waves and in the whole universe.

K. V. K.

TUBERCULOSIS IN THE CHILD AND THE ADULT. A Discussion of Pathologic Anatomy, Pathologic Physiology, Immunology, Diagnosis and Treatment.—By F. M. Pottenger, A.M., M.D., LL.D., F.A.C.P. 1934. The C. V. Mosby Company, St. Louis. Pp. 611. Illustrated. Price, \$8.50

THE book aims at a discussion of the pathologic anatomy, pathologic physiology, immunology, diagnosis and treatment of pulmonary tuberculosis. This has been dealt with in 32 chapters with 85 illustrations. A connected bibliography is given at the end of each chapter.

Before describing the childhood and adult types of tuberculosis, the author has rightly put in a discussion on the host's response to re-inoculation of tubercle bacilli. He has succeeded in giving a reasoned explanation of the response in terms of cell sensitiveness, allergy and immunity. Tuberculosis workers are now beginning to appreciate that a proper knowledge of this subject is not only essential whereby to interpret signs and symptoms but also to assess the prognosis of a case of tuberculosis. The author has rightly taken considerable space to explain the nature of tuberculo-allergy and the causation and process of tuberculin reaction, proliferative and exudative changes and the nature of cavities, although his observations have sometimes gone beyond the findings of experimental work (pp. 148 to 151). The subject of childhood infection has rightly received more attention, as the story begins in childhood and the initial and re-infections are of fundamental importance in understanding tuberculous phenomena in the adult.

The phenomena as seen in less tuberculized races, e.g., in America, South Africa and India, do not seem to have attracted the attention of the author, although the question of primary complex in adult life has justly been brought forward. Some of the findings regarding seasonal incidence (p. 141) and incidence among certain classes (p. 144) do not agree with Indian findings. A study of the various factors which bring about tissue reactions under different environmental conditions in various countries might lead us to a revision of some of our ideas on re-infection, exogenous or endogenous.

The much-neglected subject of the visceral neurology of pulmonary tuberculosis, of which the author has made a special study, has been dealt with in a special chapter. The chapter on diagnosis has been very well written. The method of sputum examination by the Dilution-Flotation-Picric acid method, developed by Dr. J. E. Pottenger, has been described as one of the best methods of examination of sputum by concentration. Practitioners would probably like the chapter on x-ray interpretation to be a little more elaborate, as roentgenology gives us information not only on the localization of the disease but also enlightens us about the pathologic nature of the lesion in terms of allergy and cell sensitiveness.

The principles for the choice of a method for the successful treatment of a case have been ably described in chapter XXIV. The various methods of compression therapy have also received attention. Practitioners would probably like some more practical hints on this subject.

The concluding chapter has been devoted to a number of illustrative case records showing different

phases of pathology and problems in diagnosis and treatment.

The subject-matter of the book forms very stimulating reading. All the latest developments on the subject have been correctly presented in an attractive form. The book is likely to be useful to all practitioners and students of medicine. The printing and paper are good and the production reflects credit on the publishers.

A. C. U.

THE CONSTRUCTION OF MODERN HOSPITALS AND THEIR EQUIPMENT: Technical and Practical Manual for Doctors, Architects, Engineers, Technicians, Staff of Administration, Students and Practitioners.—Edited by M. Schaerer, S.A. Berne (Switzerland). 1935. Published by M. Schaerer S.A. Berne, Switzerland. Pp. 676. Illustrated. Price, 40/- (Swiss francs).

It is very difficult to condense in a few lines a review of this book of over 600 pages and 900 illustrations

covering very thoroughly and with meticulous care a wide field in the construction and equipment of modern hospitals with their adjuncts such as laboratories, dispensaries, kitchens, laundries, outpatient departments, etc. The key-notes seem to be space, ventilation, lighting, cleanliness and architectural design and its perusal impresses one with the fact that among those contemplating the building of medical institutions and accommodation for their supplementary services, there should be the closest co-operation between medical authorities, architects, sanitary and electrical engineers, and a book of this kind giving a wealth of information would be very valuable to them. The instruments and equipment illustrated, most of which are designed and made by the publishers M. Schaerer S.A. Berne (Switzerland), appear to be the last word in modern design and ingenuity. Many novel features have been introduced in their construction for the comfort of the patients and the convenience of the staff.

R. T. M. H.

Abstracts from Reports

REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL FOR THE YEAR 1933-34

THE early uncertainty as to what might happen to the guilder when major currencies went off gold was held responsible last year for the large drop in the price of quinine from Rs. 26 to Rs. 19-8 per pound and was the main consideration of the year. The principal features this year, on the other hand, are a re-establishment of the confidence formerly felt in the quinine market and the maintenance of steady prices. The market price of quinine has risen some two rupees from its lowest level and stands at present at Rs. 21-12 per pound. Although there is in this commodity as marked over-production as in many others, steps are now being taken to limit output by restricting bark harvests, and the industry may be said to be in the process of adjusting itself gradually to present-day demands. A period which may run into years must, however, elapse before any degree of equilibrium can result, and only the firm hand of the monopoly stands at present as a steadying influence in the world's quinine markets. The efforts of the Kina Bureau to maintain stability are aided, it would appear, by the commonsense attitude of the Dutch planters who in adopting a policy of voluntary restriction have taken the only course other industries have found possible to the steadying of markets under present conditions of curtailed international trade. The price of the drug remains stable at a remunerative rate, and in spite of the recent advent on the market of competitive synthetic products such as plasmoquine and atebirin the belief is held that only a revolutionary discovery of some cheap and effective and at the same time easily administered product of the laboratory can disturb the pre-eminent position that quinine maintains as the world's specific for malaria. This, in any case, is the view taken by traders in the industry, and it is to be presumed that they keep themselves acquainted with developments in synthetic chemistry and can best estimate the probability of manufacturing a suitable substitute for quinine. So far there is no sign of this for, while recent additions to the list of drugs used in combating malaria may prove valuable aids in the hands of the practitioner and are to be welcomed as such, they cannot be viewed as other than expensive alternatives useful in certain cases only, but lacking the advantages quinine enjoys by its price and by the ease of its administration. Apart from its well established utility quinine holds its own as the only

drug that the layman himself can administer with safety. It is unpalatable but it is safe, and in view of the widespread nature of the disease and the poverty in general of the malarial population no drug that requires a doctor to administer it is ever likely to take the place quinine holds in alleviating suffering among the masses. This opinion is not confined to those engaged in quinine manufacture. It is a view current with the medical profession itself, the profession in India no less than elsewhere, for it found repeated expression during the discussion on supplies held at a recent conference of medical research workers in Calcutta. Although there can be no certainty in such matters, it may be taken as most probable that quinine will continue to be the main weapon against malaria. Policies for production and for a wider distribution of the drug will, therefore, continue to occupy the public mind. They are doing so now in an increasing degree. The year under review itself has witnessed the inauguration of a scheme for a wider distribution in certain selected districts in Bengal, and the Government of the Punjab have initiated a measure of mass distribution that may well prove to be the precursor of similar schemes throughout India. Attempts are at last being made to put quinine on sale at a cheap price in the smallest *hats* and bazaars, wherever indeed tobacco is on sale, and while it is too early to speak of success for the scheme it can scarcely fail to bring some measure of relief to the poorer class of sufferer. It was for this class the Cinchona Department was developed. Its products were intended for the ryot and it can feel renewed enthusiasm at the prospect of its work beginning to reap in a new manner the benefit originally intended.

The work of the department during the year under review has not been confined to the lines previously followed. The section of this report which deals with the factory will show what new directions have been taken and what duties have had to be assumed by the staff, but, generally, it may be said here that the variety of product has been extended, while good progress has been made in the routine production of a product that should be in demand in all the markets of the world where quality is of first importance. If the demand for quinine in India alone be considered there might be some difficulty in justifying great refinement in a drug that is so universally needed. It may be argued that a product less refined and at a cheaper price would better serve national ends,

especially if the refinement, as in this case, adds little or nothing to medicinal value. But with immense supplies to dispose of the department must follow a policy that will help to allow of surplus stocks being reduced, and nothing short of purification to a standard that the world's markets will accept can allow our quinine to compete with better known brands. That the Bengal department has reached the stage of influencing markets and prices may be inferred from the fact that the Kina Bureau itself is interested in the question of the use to which our stocks are to be put. Negotiations with this body have been progressing on the subject.

The factory has continued to work at high pressure with all its resources in plant and machinery forced into full play. Even larger harvests than last year's had to be dealt with in spite of which the usual efficiency of extraction has been maintained. Throughout the monsoon part of the plant had to be operated overtime at nights in order to cope with an exceptional demand for quinine tablets arising out of a severe epidemic in several districts, as also the decision to make larger stocks available at the post offices. The skilled operators and all hands concerned worked ungrudgingly and with commendable zeal during this strenuous period.

Considering the large increase in bark the production has not increased much relative to some of the post-war years, but it must be remembered that in those days half of the raw material came from the very rich Java supplies belonging to the Government of India which are not available now. But the Java bark is expensive and offers only a small margin on manufacture whereas the locally grown bark is comparatively cheap without being really poor in quality and is, therefore, financially more productive.

In recent years all the quinine has been extracted in the crude or semi-purified form and stocked as such. But during the current financial year provincial stocks of purified quinine completely gave out and enough had to be made to meet current demands. Of the total of 45,728 pounds of quinine from the Bengal barks 24,764 pounds were taken to the finished stage, the balance being left in the crude. A further 2,143 pounds of the purified product were obtained from provincial crude stocks in the course of large scale experiments on crystallization. The demand for quinine tablets was, as mentioned before, unusually heavy this year and 26,628 pounds of sulphate powder were compressed and the bulk of the product packed in the form of treatments. As to other quinine salts, 832 pounds of sulphate were converted into hydrochloride or bi-hydrochloride and 66 pounds into tartrate. Of the last item the greater part went to the Public Health Department in the form of 2-grain tablets, presumably for administration to children.

Of the cinchona febrifuge 5,434 pounds were made into tablets, the balance of the year's manufacture having been sold as powder. As in previous years, the demand exceeded the supply and was met in part by 5,054 pounds from India stocks. This reserve is, however, getting low and will no longer be available for the Bengal area of distribution. It is seldom realized that not only is the yearly supply of cinchona febrifuge limited by the quantity of the bark that can be worked in the factory, but that for every pound of this product obtained about two pounds of quinine sulphate also comes from the bark. It is fair, therefore, that cinchona febrifuge should be rationed and the amount allowed to a purchaser made proportionate to the quinine taken for it is only on this basis that the present low price of cinchona febrifuge can be maintained.

laboratory has been busy with the usual routine as well as those undertaken for the plantations for the valuation as well as cultural control. Of certain cinchona febrifuge samples was for the malaria survey of India. The

present methods of analysis for this substance are very unsatisfactory, different quinologists obtaining different results with the same sample. The matter is of some importance owing to its bearing on the totaquina question, but much as the technical staff would like to study the problem their present heavy and multifarious responsibilities including those related to audit and accounts do not leave any time for purely scientific research.

FOURTEENTH ANNUAL REPORT OF THE CALCUTTA DENTAL COLLEGE AND HOSPITAL, 1935

THE outstanding event of the year, as far as dental education in Bengal is concerned, has been the appointment by the Government of Bengal of a Dental Education and Registration Enquiry Committee, in November 1934. The committee has been asked to go into the question of dental education and registration in this province. We can justly congratulate ourselves on this development as for the past thirteen years we have been trying to organize and impart dental education in this province. We understand the committee has sent up an unanimous report to the Government of Bengal recommending the establishment of a State Dental Board and for the affiliation of this institution for teaching dentistry, the purely medical subjects to be taught in the Calcutta Medical College. We hope the Government will act on these recommendations at an early date.

The college, since its establishment in 1920, has turned out 149 dentists. Every one of them is carrying on a successful practice of dentistry in India or in the neighbouring countries. During the year under review we had 75 students on our rolls, of whom one was a girl. Twenty-five students passed the final examination of the college and received the Diploma. The students hail from all the Indian provinces. There is no dental registration law in any province of India restricting the practice of dentistry to qualified men. This fact has stood in the way of our progress. Unless we have some method of registration of dentists, there would be no incentive for students to take up a complete course of instruction in dental science.

So far we have been offering a three years' course in dentistry after matriculation from an Indian University. The Government Dental Education and Registration Enquiry Committee has recommended that the course should be one of four years and only I.Sc. passed students should be admitted. As to how soon it will materialize, it is difficult to say, but we are making arrangements that the recommendations of the committee may be given effect to without unnecessary delay.

With the exception of three full-time and two half-time members of the staff the rest are all honorary workers, drawing only a conveyance allowance. We express our thanks to all members of the staff for their work in this institution.

The cost per student per year works out at about Rs. 412. I understand the cost per student per year in the Calcutta Medical College works out at about Rs. 850. The reason why we are able to keep our cost so low is due to the system of honorary work prevailing in this institution. Lately there has been a lot of criticism of this method of work, but we see no other way out. Unless the State comes to our rescue with a generous grant, we have no other alternative. After a great deal of difficulty the Corporation of Calcutta has given us a donation of Rs. 2,950 but this has been earmarked for the Dental Hospital and a condition has been made that in return for this grant we should treat free of charge all Corporation Free Primary School children.

The present premises have become too small for our growing needs. About six months ago we selected a house in Prinsep Street with about 13 cottages of

land and were advised that after the alterations the premises could be utilized for our purpose. Accordingly we decided to buy the property and paid through our solicitors some advance money. Only a week or so ago we have been advised that the title of the said property is not quite clear, therefore we have to let that proposition go and look out for something more desirable. In any case, our removal to larger premises has become urgently necessary and we hope to move within the current year.

Our Dental Hospital is the only one in Calcutta where the benefit of both surgical and mechanical dentistry is available to the public. During the year under review the following work was done in the hospital by our students, under the supervision of the teachers.

Total number of outpatients	..	6,676
" " " surgical cases	..	113
" " " fillings inserted	..	1,466
" " " root canal treatments	..	329
" " " extractions	..	3,253
" " " prophylaxis	..	528
" " " artificial dentures supplied	..	261
" " " crown and bridge work	..	26

A large number of these are patients who would never have received any dental treatment nor had artificial dentures, were it not for this institution.

During the year under review six new dental pump chairs have been added, thus making our total available chairs in the dental clinic 23. In our present accommodation no further addition is possible. But if we have to increase our teaching facilities we must increase the number of our dental chairs.

The above abstract indicates that this institution is doing valuable pioneer work, at a remarkably low cost, and under considerable difficulties owing to lack of funds and inadequate accommodation. Dental registration is now existent in all the leading countries in the world and if the Calcutta Dental College is able to bring this about in Bengal it will earn the gratitude of the whole of India, for registration of dentists in the Presidency will no doubt be quickly followed by similar acts in other governmental areas and the practice of dentistry raised to the status it deserves throughout India.

THE KASHMIR MEDICAL MISSION OF THE CHURCH MISSIONARY SOCIETY. REPORT FOR 1934

In our notice of this hospital last year we gave an outline of its early history and in this we drew attention to the work of the two brothers Neve which began in 1882 by the appointment of Dr. Arthur Neve. In the annual report for 1934, just received by us, the announcement is made of Dr. Ernest Neve's retirement from active control of the institution, and we give below an abstract of his achievements in connection with this important work.

The chief event which we have to record in connection with our hospital this year is the retirement after forty-eight years' service of Dr. E. F. Neve.

In 1885, he graduated M.D. with gold medal and awarded the Goodsir Prize (£60). In 1886, he obtained the Fellowship of the Edinburgh Royal College of Surgeons and he left Edinburgh that same year and joined his brother, Arthur, in Kashmir. Then began a life partnership of splendid service for the sick and suffering poor of Kashmir. Between the years 1888 and 1896 the two brothers erected the whole of this hospital at a cost of less than £20,000 without any Government or other grant, a really fine achievement. The brothers worked together until 1915, a period of nearly thirty years. Dr. Arthur then went to the Great War, returning to Kashmir in 1919, and died in September of that year.

Besides the building of the whole of the present Mission Hospital, another notable work which the Neve brothers carried out was the founding, designing and building of the Kashmir Government Leper Hospital in 1891. Dr. Ernest Neve was Joint Honorary Superintendent of the Leper Asylum for a period of thirty-six years, during which time the institution increased in size and efficiency until it became one of the largest in India.

After well over half a century of medical and surgical practice, forty-eight years of which were in connection with the Kashmir Medical Mission, he retired on 31st March, 1934.

While quite retired from all medical and surgical practice, Dr. Ernest Neve's name is still retained as our Honorary Consulting Surgeon and he still gives us valuable help as Honorary Treasurer, and keeps in touch with the work by visiting the hospital twice a week to take services in the church and to preach in the wards and outpatient department.

From perusal of the report we note that the valuable work of the Kashmir Medical Mission is continuing with unabated energy though hampered in recent years by a decreased income.

Just about the time that the annual report arrived we received notice of a special appeal on behalf of this hospital because of serious loss of income both from a falling off in subscriptions from England and the loss of the consultation fees which Dr. Ernest Neve earned and paid to the hospital. The work of this mission hospital has always been outstanding among mission hospitals and we feel it would be a matter of regret if its work was seriously curtailed for lack of funds. Therefore we invite those of our readers who feel so disposed to send donations to the superintendent of the Mission Hospital, Srinagar, Kashmir.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF THE PUNJAB DURING THE YEAR 1933. BY KHAN BAHADUR DR. K. A. RAHMAN, O.B.E., M.B., CH.B. (EDIN.), D.P.H. (LOND.), DIRECTOR OF PUBLIC HEALTH, PUNJAB, TOGETHER WITH THE REPORT ON SANITARY WORKS. BY D. A. HOWELL, M.I.C.E., SUPERINTENDING ENGINEER, PUBLIC HEALTH CIRCLE, PUNJAB

AN abnormal feature during the year 1933 was the severe flooding of three districts in the Ambala division, as a result of exceptionally heavy rains towards the end of the monsoon, with the result that mortality from fever was the highest of the decade.

Mainly for the above reason there was an increase in the provincial death rate from 24.7 to 28.2, the total number of deaths (660,542) being higher than in any year since 1926 when, besides high mortality for fever, there was also a serious plague epidemic. But, as the birth rate (1,042,624) showed a rapid leap upwards, being the highest yet recorded, the population increased from 24,189,503 to 24,571,585. A feature of the birth rate is, as usual, the excess of males over females, the proportion during the year under report having been 111.6 to 100 as against 111.9 in the preceding year. It is regrettable that the infant mortality rate, 192.55 per thousand, exceeded that of any year since 1926.

The special thanks of Government were conveyed to the Public Health Department and other officials in connection with the eminently satisfactory arrangements for the Sun Eclipse Fair held at Kurukshetra in the Karnal district in August 1933. The number of pilgrims exceeded five lakhs, many of whom came from cholera-infected areas. Fortunately, however, owing to careful dispositions for conservancy and water-supply arrangements, there were only three imported cases of cholera of which one was fatal.

Cholera.—Twenty districts were infected during the year, but mortality was unduly low, there being only 160 deaths and 238 seizures as compared with 614

deaths and 1,119 seizures in the year preceding. The success attending anti-cholera measures at the Solar Eclipse Fair has been mentioned above. It is thus apparent that the public health authorities' anti-cholera measures have now attained a very high degree of success.

Smallpox.—The mortality from this cause showed a considerable increase, the number of cases rising from 5,184 to 11,626, every district in the province being affected. It is explained in the report that this periodic rise every five years or so is inevitable, but that it is reassuring that the peak of the curve of the disease attained a considerable lower level than at the last similar epidemic in 1926 when 17,595 deaths were recorded. The strenuous efforts to combat the disease are described in detail in the report, and the Government is glad to learn of the co-operation of other departments, especially the education, with the public health department. The great majority of deaths from this cause were in small children, 3,534 being in children under one year of age and 5,332 in those between one and ten years. It is noticeable that the number of vaccination operations fell from 3.6 millions to 3.2 millions. These figures are for the years ending 31st March, 1933, and 31st March, 1934. It is explained in the report that in the previous period smallpox mortality was higher, and that this accounts for the larger number of vaccinations.

A decrease in the number of vaccination operations considerably increases the cost of each operation. Thus the decline in the number of successful operations performed by the staff of the local bodies raised the cost from Re. 0-2-0 to Re. 0-2-5 and in the case of the special vaccination staff of the public health department from Re. 0-7-4 to Re. 0-10-4.

Plague.—The plague mortality showed a further decrease falling from 2,003 to 1,789. This is gratifying, as fear was expressed in last year's review that the slight increase recorded for 1932 might portend a further rise. More than half of the mortality occurred in the Hoshiarpur district, which was one of the three districts mostly affected in the previous year. There was a considerable increase in the number of plague inoculations, which amounted to 133,743 as against 91,600, the greatest number of inoculations being in the district chiefly affected, Hoshiarpur.

Malaria.—As above remarked the climatic conditions of the province were particularly conducive to malaria, and mortality from fevers, which consisted mainly of this disease, was abnormally high (460,731). The strenuous efforts made to combat it, particularly by distribution of quinine and cinchona from tubes maintained in rural areas, are described in the report. In connection with the relief work in operation for a considerable period in Rohtak, Karnal and Gurgaon, an attempt was made to give a four days' quinine treatment course to patients, and appears to have been successful.

Leprosy.—An instructive leprosy survey was carried out during the year throughout the Kangra district, which is probably the only endemic area in the province, and also in part of the Lahore district including Lahore city. It was subsequently decided that Dr. Malhotra, the medical officer of the Leper Home, Palampur, should also be entrusted with the work of the district leprosy officer of the Kangra district. Seven outdoor clinics have been opened in the tahsil Dera Gopipur of that district where free treatment is administered, and it is confidently expected that the treatment of the disease in its early stages will ultimately lead to its eradication. In the Lahore district 22 cases were discovered, 19 in Lahore city itself; and of the latter, seven were residents of the United Provinces and 8 were beggars who have migrated from the United Provinces. Against these no action can at present be taken as the Lepers Act has not yet been extended to this province.

Ankylostomiasis.—The special investigation into the prevalence of hookworm infection in the Shakargarh

tahsil of the Gurdaspur district produced important results, and it was found that in some villages over 50 per cent of inhabitants were suffering from the complaint. A scheme for mass treatment was sanctioned, and is being carried out under the supervision of the epidemiologist. Probably this insidious disease is prevalent and unnoticed in other areas, and it is intended to extend the investigation to other districts.

Maternity and child welfare.—The number of health centres showed a considerable increase during 1933, the total number in the province rising to 52. Of these, 20 are maintained by the Red Cross Society, 13 by District Boards, 10 by voluntary associations other than the Red Cross Society and 9 by Municipal Committees; and 35 of them are in rural areas. Most of them during the year were inspected by the inspectress of health centres, who is also the principal of the Punjab Health School, and the work at each centre proceeds on the same lines as at the Punjab Health School centre. During the year the centres were visited by 11,264 expectant mothers for advice, medical aid being called for in 343 cases. It is also a matter for satisfaction that the number of *dais* under training rose from 1,405 to 1,779, and during the year 575 of these obtained the Indigenous *Dais'* certificate of the Punjab Central Midwives Board, and of 14,222 confinement cases attended by trained *dais* over 5,000 were supervised by lady health visitors.

Urban sanitation.—As in the previous year, financial stringency prevented Government giving grants for new schemes, and expenditure by local bodies on conservancy and drainage was also restricted. Rupees 1,75,000 were allotted to the sanitary board in connection with urban sanitary works, and this went towards works already in progress, but only Rs. 1,35,000 was actually expended.

A list of a large number of very important schemes continued or completed during the year is given in the report supplied by the Superintending Engineer, Public Health Circle. This part of the report also contains a detailed account of the inspection of water supply and conservancy works of local bodies throughout the province carried out by the public health staff; and in this connection the Government regrets that it has again been found by the department that some local bodies fail to maintain sanitary works in a satisfactory state. It is particularly unfortunate that this continues to be the case, in view of the enormous increase of sanitary works in towns during the last 13 years, since the Sanitary Engineer to Government (now Superintending Engineer, Public Health Circle), whose duties were previously advisory and consultative, undertook the actual construction of important sanitary schemes. Thus, the total value of public health engineering works, wholly or partly completed by the end of 1933, was about 350 lakhs, or three times the value of such work in 1920; the total horse-power of mechanical plant installed for sanitary works is about 8,000, or over twelve times as great as that of the plants existing in 1900.

Rural sanitation.—As in the case of urban sanitary schemes, there were no new rural water-supply schemes started, though work continued on all schemes already in progress. Under the ægis of the public health department about Rs. 56,000 were spent by district boards and villagers on the cleansing of wells and on the construction of parapets. An interesting account is given in the report of propaganda work and 'uplift' meetings held throughout the province. The work done in Ambala, Ludhiana and Ferozepore districts in particular was very considerable and, from the figures supplied in the report, it would appear that the condition of a large number of villages in those districts must have been vastly improved.

Conclusion.—The Government deeply regrets to have to record the death, after he had been in charge of the department for ten months, of Major R. C. Malhotra, I.M.S.; he was succeeded as Director of Public Health by Khan Bahadur Dr. K. A. Rahman.

FIRST TREATMENTS IN MEDICINE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I shall be obliged if you will kindly publish in your next issue this mild remonstrance against your reviewer, K. V. K.'s wholesale condemnation of my recently published 'First Treatments in Medicine'.

To begin with, he is wrong in his statements. He says I recommend the use of carbolic acid for malaria and amœbic dysentery (implying I recommend it alone), and *make no mention of the efficacy of quinine or emetine*. I do no such thing, and I don't suppose any medical man in his senses would recommend carbolic acid by itself for such ailments, but, *combined with quinine*, as in the prescription given, *where quinine is specially included*, it is a very potent remedy, though K. V. K. may not know it, and has completely cured many cases. Why it should do so in such combination, when neither would alone, I do not positively state, but the efficacy of such combinations is common, as K. V. K. must be aware.

K. V. K. has apparently only scanned the preface cursorily. Let me quote: 'A certain amount of knowledge.....has been presupposed'. Every three years' student even must be aware of the value of emetine, antitoxin, arsenical and bismuth preparations, etc., but they are not always immediately available or procurable. The drugs I have mentioned usually are, and can be used as 'First Treatments', while others are being procured. Line 11, again of the preface, specially says that these treatments are 'suggested as a start', for those who may be befogged as to what to do. Competent practitioners like K. V. K., especially those living in large towns where any desired kind of medicine is available at once, can, of course, go ahead with any kind of treatment they know of and prefer.

The whole object of the book is to suggest, especially to beginners, a 'First Treatment' (not a complete or final one) in any particular case, and, as again suggested in the preface, 'with the almost endless treatments that exist for some complaints', only one or more have been given as a start, varying in some cases with the stage at which the patient is first seen. In some instances other treatments might, of course, have been given instead.

I really don't think K. V. K.'s predictions of disaster are likely to come to pass!—Yours, etc.,

G. F. ROWCROFT,
Colonel.

COONOR,
16th April, 1935.

[We have seen this book and on the whole are in agreement with our reviewer. We note that emetine, antitoxin, etc., have been omitted as being likely to be known by the most experienced practitioner and also probably not available immediately, whereas insulin without any information as to dosage or method of administration is given under the treatment of diabetes. We think the former drugs more likely to be easily obtainable than the latter, and that insulin is hardly to be classed as a 'first treatment' according to the author's definition.—EDITOR, I. M. G.]

TETRACHLORETHYLENE AND ITS EFFECT ON TAPEWORM

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Patient, a convict, came with the complaint of intestinal colic and progressive anæmia. He was passing proglottides *per anum* and had been losing weight. The stool was examined under the microscope and showed ova of *Tænia*.

He was given a course of extract *filiis liquidum* 1½ drachms in capsules in divided doses followed and preceded by purgatives. The result was a tapeworm of 3 feet length expelled without its head.

The patient did not improve and his complaint remained the same. After a fortnight, as directed by the superintendent of the Jail, a course of tetrachlorethylene 4 c.cm. with two ounces of saturated magnesium sulphate solution was administered and the patient expelled a worm 10 feet in length with its head.

Since then the patient is putting on weight and made an uneventful recovery. I should like to know if tapeworm has been treated with this drug previously. To my mind it appears to be very effective.—Yours, etc.

MD. AFSAR,
Sub-Assistant Surgeon In-charge
of District Jail Hospital.

JOREHAT, ASSAM,
25th April, 1935.

[Note.—Tetrachlorethylene has been tried on several cases of tapeworm infection at the Carmichael Hospital for Tropical Diseases, Calcutta, without apparent effect (*Indian Med. Gaz.*, Vol. LXVI, p. 667) but carbon tetrachloride has been found very good for removing these parasites (*Indian Med. Gaz.*, Vol. LXVI, p. 670).—EDITOR, I. M. G.]

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL C. E. PALMER, Officiating Inspector-General, Civil Hospitals and Prisons, Assam, is confirmed in that appointment, with effect from the forenoon of the 15th February, 1935.

The Viceroy and Governor-General has been pleased to make the following appointments on His Excellency's personal staff:—

To be Honorary Surgeons

Lieutenant-Colonel G. G. Jolly, C.I.E., *vice* Colonel A. H. Proctor, D.S.O., vacated. Dated 18th March, 1935.

Lieutenant-Colonel R. Hay, an Agency Surgeon, is posted as Residency Surgeon and Chief Medical Officer in Baluchistan, with effect from the afternoon of the 20th March, 1935.

Major J. G. Bird, an Agency Surgeon, on return from leave is posted as Civil Surgeon, Quetta, with effect from the 29th March, 1935.

The probationary appointment of the undermentioned officers is confirmed:—

Captains

R. L. Haviland Minchin.

W. G. Kingston.

J. Edis-Meyer.

T. K. White.

R. De Soldenhoff.

C. J. Hassett.

R. R. Prosser.

E. Parry.

W. G. Kennedy.

P. I. Franks.

B. F. B. Russell.

The services of Captain D. P. Nath are placed at the disposal of the Government of Bihar and Orissa for employment in the Jail Department, with effect from the date on which he assumes charge of his duties.

With reference to previous notifications in so far as the undermentioned officers are concerned their position on confirmation will be as shown below:—

Captain H. A. Ledgerd.
 Captain S. Ahmad.
 Captain C. C. Kapila.
 Captain W. W. Laughland.
 Captain T. F. O'Donnell.
 Captain J. White.

PROMOTIONS

Majors to be Lieutenant-Colonels

A. H. Shaikh. Dated 5th March, 1935.
 R. M. Kharegat. Dated 11th March, 1935.
 J. C. Pyper, O.N.E. Dated 15th March, 1935.

LEAVE

Major-General Sir Robert McCarrison, Kt., C.I.E., K.H.P., an officer of the Medical Research Department on foreign service under the Indian Research Fund Association, is granted leave pending retirement, for 5 months, with effect from the 18th March, 1935. His services are placed at the disposal of the Director-General, Indian Medical Service, from the same date.

Lieutenant-Colonel Stevenson, an Agency Surgeon, is granted 8 months' leave, with effect from the afternoon of the 20th March, 1935.

On termination of his appointment as Officer on Special Duty in the office of the Director-General, Indian Medical Service, Lieutenant-Colonel G. G. Jolly, C.I.E., Deputy Director-General, Indian Medical Service, is granted leave on average pay for 4 months and 4 days combined with leave on half average pay for 20 days, with effect from the 22nd March, 1935.

Major S. L. Bhatia, M.C., Professor of Physiology and Histology, and Dean, Grant Medical College, Bombay, is granted leave for 5 months and 24 days, with effect from the 4th June, 1935, with permission to prefix to the leave the College vacation from 8th April, 1935, to 3rd June, 1935.

RETIREMENTS

Lieutenant-Colonel R. G. G. Croly, on account of ill health, 4th February, 1935.

Lieutenant-Colonel F. C. Fraser, 15th February, 1935.

Lieutenant-Colonel R. B. S. Sewell, C.I.E., 5th March, 1935.

Lieutenant-Colonel F. Oppenheimer, 9th March, 1935.

Notes

THE Q-RAY ELECTRO-RADIUM COMPRESS

As soon as it was discovered that it was the combination of radio-activity and warmth that was responsible for cures at various Spas, experiments took place in an endeavour to combine these two healing agents, radium and warmth, in such a way as to make them available for those sufferers who, for economic reasons, were unable to travel. These experiments were eventually crowned with success.

In 1928 an International Radiological Congress was held in Vienna, to which came many professors and scientists to discuss their experiences in radium therapy. At this congress was demonstrated the first Electro-Radium Compress, the ordinary type which, for the first time, united in a simple, safe, portable and convenient form, the action of the rays emitted from radium with the action of warmth.

This apparatus is supplied by the Radium Electric Limited, 24, Grosvenor Gardens, London.

WATSON'S MICROSCOPE CATALOGUE

We have received a copy of Watson's microscope catalogue, parts 1 and 2. This contains the familiar items that are usually found in Watson's well-known catalogue, but it has been brought thoroughly up to date.

The chapters on the optical parts of the microscope have been completely re-written, and on page 17 is printed a table showing the initial and combined magnification of the various objectives and eyepieces, micrometric values and actual fields of view. They have given an introduction to condenser technique, while a very full description of the construction of their microscopes and full particulars of the unit design of the body tube, interchangeable parts, etc., will also be found. The Bactil, Patna and Royal models have been re-designed. The optical-bench system is now applied to all instruments, and the low power binocular microscope on pages 113 and 116 is worth special attention.

In the second part of the catalogue will be found an entirely new series of lamps, two interesting projectors, an insect holder, and a very full list of stains and reagents, all these being of British manufacture.

This catalogue is once more far more than an illustrated price list; it provides many items of great interest to all microscopists.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ARTERIAL VERSUS VENOUS BLOOD SUGAR*

ARTERIO-VENOUS SUGAR DIFFERENCE AS A CRITERION OF THE SEVERITY OF DIABETES

By J. P. BOSE, M.D., F.C.S. (Lond.)

(From the Diabetes Research Department, School of Tropical Medicine, Calcutta)

Historical.—It was in 1848 that Claude Bernard first started the theory that sugar was only present in the blood drawn from the hepatic vein and on the right side of the heart, and was not present in any other part of the circulating blood.

This was not seriously questioned until 1856 when Chauveau, having made extensive studies on blood-sugar estimation, came to the following important conclusions:—

(1) That sugar was present in all parts of the circulating blood.

(2) That the arterial blood contained more sugar than the venous blood.

(3) That the sugar content of the blood was constant and persisted even after prolonged fasting.

Chauveau's observations were corroborated and established by workers such as Frerich, Figuier and others.

The micro-chemical method of blood analysis was introduced by Bang in 1913 resulting in a widespread clinical application of *capillary* blood-sugar determination in quantities of 0.1 c.cm. only. Almost at the same time Lewis and Benedict described a method of blood-sugar analysis with 2 c.cm. of venous blood. Both of these methods, eminently practical and requiring small quantities of blood at a time, gave a great impetus to blood-sugar determination in the clinics of Europe and America. Bang's method was generally adopted in Europe while Lewis and Benedict's method was followed in America. The results of the blood-sugar studies by European and American observers, however, often showed discrepancies and disagreements and were followed by argumentative discussions and comments.

Introduction.—Having used both the capillary (arterial) and the venous blood for blood-sugar investigations during the last fifteen years, the author was puzzled in the beginning at the discrepancy in the results that were obtained. No satisfactory explanation at the time was forthcoming as to why there was a difference in

the results of the glucose tolerance test done on the same patient by the arterial and venous methods. It was not long, however, before the full significance of such difference was realized and attempts have since been made to turn this fact to practical usefulness.

The author has made a study of the distribution of sugar in the blood (both capillary and venous) of diabetic and non-diabetic subjects and, as a result of such study, the immense value of the determination of the arterio-venous sugar difference (A-V difference as it is called), either at the fasting stage or during active sugar absorption, as an important and reliable guide for the determination of the state of carbohydrate metabolism of the individual has, in his opinion, been established. The estimation both of the arterial sugar and the venous sugar in cases of diabetes mellitus will give a truer and better indication of the nature of the disease than estimation of the venous blood sugar alone, and the determination of the arterio-venous sugar difference will give a much better indication of the severity of the disease and the line of treatment to be adopted in individual cases, more particularly as regards the indications for insulin treatment.

The fasting levels of sugar in arterial and venous blood

The data which have been obtained as regards the fasting level of sugar present simultaneously in the arterial and venous blood in healthy normal subjects and in diabetic individuals, and as regards their arterio-venous difference, may be summarized as follows:—

In normal healthy individuals—(a) the average level of sugar content in the arterial blood was found to be 95 mgm. and that in the venous blood was found to be 92 mgm. per 100 c.cm.;

(b) the average arterio-venous sugar difference was found to be +3 mgm. per 100 c.cm. of blood. In no case was a negative arterio-venous difference obtained.

In cases of diabetes, mild, moderate and severe—(a) the average fasting level in the arterial blood in mild cases was 156 mgm. and in the venous blood 153 mgm., the arterio-venous difference being +3 mgm. per 100 c.cm. of blood;

(b) the average fasting level in the arterial blood in moderately severe cases was 355 mgm., and in the venous blood 358 mgm., thereby creating a *negative* arterio-venous difference of —2 mgm. per 100 c.cm. of blood;

(c) the average fasting level in the arterial blood in severe cases was 469 mgm., and in the venous blood 475 mgm., thus creating a marked negative arterio-venous difference of —6 mgm. per 100 c.cm. of blood.

From the above data it is clear—

(1) that as far as the fasting arterio-venous sugar difference is concerned, mild cases of

* A more detailed and systematic study on the same subject has been sent for publication in the form of a paper entitled 'Arterio-venous sugar difference in diabetes mellitus: Its value in adjudging the severity of the disease' in the *Indian Journal of Medical Research* and will appear in the July number of the journal.

diabetes do not differ materially from normal subjects;

(2) in moderately severe cases of diabetes, the sugar content in the venous blood exceeds that of the arterial blood, thereby creating a negative arterio-venous difference;

(3) the difference between the moderate and the severe cases of diabetes is a matter of the degree of arterio-venous sugar difference obtained, notwithstanding the height of the fasting level of sugar.

Though the determination of the arterio-venous sugar difference in severe cases of diabetes in the fasting state may give us some idea of the severity of the disease, a much more definite and clear idea is obtainable by studying the arterio-venous sugar difference after a glucose meal.

Effect of ingestion of glucose on the arterio-venous sugar difference

The data which have been obtained as regards the effect of ingestion of glucose on the arterio-venous sugar difference in healthy normal individuals and in diabetic subjects may be summarized as follows:—

In normal healthy subjects—

(a) the arterio-venous sugar difference is negligible in the fasting stage, the average being +3 mgm. per 100 c.cm.;

(b) after the glucose meal, the arterio-venous difference rises, the maximum being obtained at the end of one hour after the meal. In five cases, the peak was obtained in a half hour's time;

(c) the average arterio-venous difference obtained in the one-hour period was +35 mgm., the variations ranging from a minimum of +26 mgm. to a maximum of +45 mgm. per 100 c.cm. of blood;

(d) the arterio-venous difference rapidly decreases one hour after the glucose meal, coming almost to the post-absorption level at the end of two and a half hours.

In mild cases of diabetes—

(a) the fasting arterio-venous difference did not differ materially from the normal cases;

(b) after the glucose meal, the arterio-venous difference was much less marked than in the normal case, the greatest difference (+13 to +20 mgm. per 100 c.cm. instead of +26 to +45 mgm. as in normal cases) occurring at the end of one hour after the meal;

(c) the fall in the sugar content of both the arterial and the venous blood began at the end of one and a half hours (instead of one hour as in normal cases);

(d) the arterio-venous difference regained the original level at the end of two and a half hours.

In severe cases—

(a) the fasting arterio-venous difference was almost always on the negative side;

(Continued at foot of next column)

TEBETREN IN INDIAN STRAINS OF MALARIA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

B. SEN, B.Sc., M.B.

and

S. K. GANGULI, M.B.

Department of Pharmacology, School of Tropical Medicine, Calcutta

ALTHOUGH for the last three hundred years quinine has enjoyed the reputation of being the best remedy for malaria, its administration is attended with certain drawbacks: (i) It has to be administered in large doses and for a prolonged period (10 grains twice daily for 10

(Continued from previous column)

(b) after the glucose meal, there were at least five cases in which the rise in the sugar content of the arterial blood exceeded that of the venous blood, thus converting the initial negative arterio-venous difference into a positive one, though of a small degree. The other cases retained the negative difference throughout the test.

From the above, it is reasonable to conclude that the magnitude of the difference between the sugar content of the arterial blood and the venous (positive arterio-venous difference) after glucose ingestion is the best indication of the rate of glucose utilization in the tissues. In diabetes, it should be remembered, the power of glucose utilization in the tissues is defective according to the degree of the severity of the disease. That explains why the degree of positive arterio-venous difference becomes less and less as the severity of the disease increases and, in the severe cases, even a negative arterio-venous difference is obtained, i.e., the venous sugar level rises higher than the arterial sugar. The reason for this is probably that there are times when the tissues are discharging more sugar into the venous blood than they are receiving from the capillary blood. The tissues lose the power of retaining the sugar that is stored in them and under the stress of the sudden flooding by extra sugar brought to them by the arterial blood, after a glucose meal, not only let it flow through without change but actually give up to the venous blood a little or a good deal of the sugar retained by them.

The above explanation receives some corroboration from the results of some of the experiments which the author is carrying out at present, viz, the action of insulin on the arterio-venous sugar difference in normal and diabetic subjects. It has been found, for example, that insulin not only helps the tissues to retain the sugar stored therein but often gives its aid in abstracting some of the sugar from the arterial blood, thus converting a negative arterio-venous difference into a positive one.

consecutive days), (ii) it is comparatively less effective in curing benign tertian infection, (iii) it has no effect on the crescentic gametocytes of *P. falciparum*, and (iv) it produces certain nervous symptoms and hæmoglobinuria in a small number of cases. Acton, Curjel and Dewey (1921) and Rennie, Acton and others (1921) observed that the alkaloids of cinchona bark other than quinine possess antimalarial properties and showed that 10 grains of cinchona febrifuge (a mixture of all alkaloids), given twice daily for ten consecutive days with a dose of an alkaline mixture half an hour before, cured fifty per cent of benign tertian infections, whereas with quinine the cure rate was never above thirty per cent.

The shortage of quinine during the Great War led to the synthesis of a number of antimalarial compounds and the drawbacks of the use of quinine, mentioned above, also stimulated research in this direction. Though these synthetic preparations cannot totally replace cinchona alkaloids yet, some of them have been shown to be just as effective and they undoubtedly serve as very useful adjuncts in the treatment of malaria. The synthesis of plasmochin by Schulemann in 1926 marked a distinct advance in this connection. Although further experience has shown the drug to be more toxic than was at first supposed, a total of 0.04 to 0.06 gm. spread over a period of two or three days produces a rapid and marked effect on the gametocytes of *P. falciparum* strains in India. They show signs of degeneration soon after plasmochin is started and totally disappear on the completion of the course described above. Any parasites left lose their viability and are incapable of further development in the mosquito host. Green (1929) has cured quartan malaria with plasmochin alone. Freiman (1929) as well as Stern (1929) have also treated malaria with plasmochin alone but our experience with Indian strains, however, is that the dosage necessary to produce any marked effect on these strains is large enough to produce toxic effects. Symptoms of poisoning, such as pain in the abdomen, cyanosis, cardiac irregularities, etc., have occurred with such doses, which necessitated the immediate discontinuance of the drug.

The next achievement in the chemotherapy of malaria was the synthesis of atebirin in 1929. Chemically this preparation is the dihydrochloride of an alkylamino-alkylamino-acridine derivative. Its action on malarial parasites closely resembles that of the cinchona alkaloids. Unlike plasmochin, however, it is a comparatively non-toxic drug. Certain untoward symptoms have been recorded while treating patients with atebirin but they are not serious. Comparative studies of atebirin and the cinchona alkaloids, so far as their effects on malarial parasites are concerned, have been made by various workers. The general opinion is that though atebirin can

not yet totally replace the cinchona alkaloids in mass treatment of malaria in this country, it is a very effective drug. It is particularly useful in those patients who are susceptible to quinine. Some also regard it as a prophylactic against malaria as it is slowly eliminated from the system.

Malarcan is another drug which has a definite action on malarial parasites. It is said to be a compound of a stereoisomeric base of methyl-eupreine with methyl-acridinium chloride and hydrochloric acid. It therefore appears to be a derivative of quinine or quinidine. Its action in some ways resembles that of atebirin but it has to be given for a longer period. The usual dosage is 9 to 12 tablets a day up to 80 or a 100 tablets. The only toxic symptoms which were noticed during the administration of the drug were flatulence, anorexia and slight ringing in the ears which disappeared with the stoppage of the drug.

The discovery of the antimalarial properties in acridine derivatives was utilized by Howard and Company in preparing 'tebetren' which they have recently introduced as a remedy for malaria. It is a combination of acridine and quinine derivatives with a derivative of cholic acid. The idea underlying this combination was to attain the maximum effect without the untoward symptoms which are usually manifested when quinine or atebirin are administered alone. Green tried this drug on a series of patients and stated that it destroys crescents. We took up the following investigation in order to study its effect on the Indian strains of malaria.

The investigation was carried out on a small series of twenty-two patients in the Carmichael Hospital for Tropical Diseases. Adult male patients giving a history of repeated attacks of malaria were admitted into the hospital under the senior author. Except in cases showing urgent symptoms the antimalarial treatment was withheld for a few days in order, firstly, to identify the species of the infecting parasites by means of daily blood examination and, secondly, to select only those cases which did not show any tendency to spontaneous recovery. Daily estimations of the number of parasites per c.mm. of blood were made during this period. Administration of tebetren was started when the parasite count was fairly constant for two or three days. Three tablets were given thrice daily for five consecutive days. The blood was examined daily for malaria parasites while tebetren was being administered and the effect of the drug was studied on (i) temperature, (ii) the sexual and asexual forms of parasites, and (iii) the time taken for their disappearance from the peripheral blood. Any untoward symptoms produced were carefully recorded. The patients were kept under observation for a fortnight after the treatment was completed and, if the blood examinations were negative, a

cultural examination was also done. No special precautions were observed during the course of treatment except that constipation if present was relieved with a mild purgative. The results have been analysed and are given in the table.

Perusal of the table shows that in cases of infection with *P. falciparum* the asexual forms are destroyed within three to five days, but the sexual forms remain unaffected (cases nos. 1, 2, 4, 5, 6, 7, 10, 12, 13, 16 and 21). In cases of infection with *P. vivax* both the asexual and sexual forms disappeared from the peripheral blood within three to five days (cases nos. 1, 5, 9, 10, 11, 15, 16 and 17). The effect of tebetren on both the asexual and sexual forms of *P. malarie* was much less marked and in cases nos. 1, 2, 3, 8 and 14 the parasites persisted for a comparatively longer period. In case no. 14 the plasmodia persisted for seven days after completion of treatment. The cure rates with this drug on the three species of parasites are as follows:—

P. vivax .. 6 out of 9 (66 per cent), one of whom left hospital on the 13th day after treatment.

P. falciparum .. 8 out of 12 (66 per cent), one of whom left hospital on the 5th day after treatment.

P. malarie .. 3 out of 6 (50 per cent).

The following cases are of special interest in this investigation. Case no. 3 was admitted with quartan infection, but the relapse showed benign tertian infection instead of quartan. Case no. 18 also had quartan infection but the relapse showed both quartan and malignant tertian. In the case of no. 9, *P. vivax* and *P. falciparum* were both present on admission but only *P. falciparum* was found when treatment was started; the relapse which occurred on the 23rd day showed *P. vivax* only. The explanation appears to be that cases nos. 3 and 18 had a latent benign tertian and malignant tertian infection respectively which could not be controlled by tebetren. Similarly in case no. 9 the malignant tertian infection had become latent by the time treatment was actually started, and possibly remained unaffected. These three cases show that this drug like others does not reach the parasites in the internal organs in sufficient concentrations to destroy them completely and when relapse occurred they became active and appeared in the peripheral circulation.

The untoward effects which were met with in a certain number of patients during the course of trials with tebetren were anorexia, a sense of uneasiness in the epigastric region and flatulence. One or two patients complained of some disturbance in sleep. Case no. 22 showed

THE TREATMENT OF OBSTRUCTION OF LACRIMAL DUCT AND CHRONIC DACRYOCYSTITIS

By JADAVJI HANSRAJ, D.O.M.S. (Eng.)
L.M. & S. (Bombay)

Bombay

OBSTRUCTION of the lacrimal duct is generally due to chronic dacryocystitis and subsequent fibrosis, stricture or stenosis of the lacrimal duct. It is not necessary to give the pathological factors which bring about the condition, as they can be found in any textbook on ophthalmology. On the other hand I propose to discuss the treatment in some detail.

Treatment

The measures adopted to cure this condition are:—

- (1) Syringing the lacrimal sac with antiseptics or astringents.
- (2) Dilating the stricture by passing graduated probes through the lacrimal duct.
- (3) Excision of the lacrimal sac—
 - (a) by the usual-external method.
 - (b) by the intranasal method (the operation goes by the name of West intranasal dacryocystotomy).
- (4) Stricturectomy by Poulard's method.
- (5) Toti's or Dupuy Dutemps' operation—in other words establishing a permanent drainage of the lacrimal sac into the nasal cavity (dacryocysto-rhinostomy).

(Continued from previous column)

sensitiveness to tebetren and the drug had to be stopped after the first day.

Summary.—Tebetren resembles quinine and atebirin in its action on Indian strains of malaria. It destroys the asexual and sexual forms of *P. vivax* and *P. malarie*, but only the asexual forms of *P. falciparum*. Its action on *P. malarie* is comparatively slower and less potent. Like atebirin it is not unpleasant to take, but the drug has to be given in much larger doses than atebirin. As compared with cinchona alkaloids the drug is much more expensive and appears to have no particular advantage over them.

The advantages and disadvantages of the different methods as observed by me in my experience of thirty years are as follows :—

(1) *Syringing the lacrimal sac*

The only condition in which a radical cure can be brought about by this method is congenital stenosis or obstruction of the lacrimal duct in the newborn; and in those conditions in the adult in which the obstruction of the lacrimal duct is not complete. In cases of obstruction of the nasal duct in the newborn the cause is a tag of mucus getting impacted in the duct. In these cases syringing the sac with a mild antiseptic or even saline solution is sufficient to bring about a permanent cure.

In adults when the obstruction is not complete daily syringing of the sac keeps the condition in check for the time being but ultimately when the obstruction is complete, syringing the sac is practically useless.

In all other cases syringing the sac never brings about a cure.

(2) *Probing*

Probing has been resorted to as a means of curing this condition but in the experience of most surgeons including myself this is disappointing.

There is temporary relief in most cases, but in the long run the condition becomes worse and total obstruction of the duct is the result.

(3) *Excision of the sac*

This operation is resorted to by most of the surgeons in India as well as in Europe. If the operation is done well and if no piece of the sac is left behind after the operation cure is complete, but the after-effects are very annoying and cause discomfort to the patient. The continuous epiphora that we find in most of the cases is a source of permanent trouble.

(4) *Poulard's stricturectomy*

I have been doing this operation for the last eighteen months. Up to the present time I have done twenty and in eighteen cases the cure is complete. Only in one case I had to resort to excision of the sac as it was impossible to pass the stricturectomy knife into the lacrimal duct. In this case it was observed at the time of doing the excision that the thickening of the bone was so great that there was no passage left for the knife, not even for the smallest probe.

The advantages of this operation are that the sac is left intact and there is no epiphora.

The operation itself is comparatively simple as will be seen from the following brief description :—

Technique of the operation

(a) The inferior punctum is touched with a ten per cent cocaine solution to which a few drops of adrenaline chloride solution have been added.

(b) The skin over the lacrimal sac is touched with tincture iodine rectificatus.

(c) The eye washed with 1:5,000 perchloride of mercury lotion.

(d) A few drops of five per cent cocaine solution with adrenaline chloride injected into the sac after dilating the inferior canaliculus.

(e) Two per cent novocaine solution with a little adrenaline chloride solution injected into the sac in two places, viz, in the region of the fundus and near the lacrimal duct.

(f) The anaesthesia is complete after 10 minutes.

(g) Wash the sac with rivanol solution 1:5,000.

(h) Poulard's stricturectomy knife is passed through the inferior punctum and the inferior canaliculus is split open.

(i) Poulard's probe (no. 2) is forced through the duct. Care should be taken that no false passage is made.

(j) Poulard's stricturectomy knife is passed through the slit canaliculus into the sac and then through the duct. A turn of 90 degrees is to be given to the knife and the stricture in the duct is cut with the edge of the knife.

(k) The knife is taken out and probe no. 14 is passed through the duct.

If the stricturectomy has been properly done the probe will pass without any resistance. It is kept there for about three minutes.

It will be noticed at this stage that while it was found difficult to pass no. 1 or no. 2 probe before stricturectomy, probe no. 14 slips through with ease after stricturectomy.

(l) A drop of argyrol solution is put into the eye and a pad and bandage applied. The bandage is kept on for twenty-four hours only.

After-treatment

On the fourth day after the operation the sac is washed with rivanol solution 1:5,000 and two or three drops of ten per cent cocaine solution with a little adrenaline are injected into the sac.

Five minutes after the injection of cocaine a gum elastic bougie no. 14 is passed through the divided stricture and kept *in situ* for about two minutes.

If it is not possible to pass the bougie, the metal probe may be passed and kept there for about two minutes.

This treatment is repeated every fourth day for the first four treatments and then every sixth day for the next two treatments.

After six treatments the cure is complete.

Complications and sequelae

There are three important complications that may occur during the operation :—

- (i) False passage.
- (ii) Haemorrhage.
- (iii) Failure to pass the probe.

(i) False passage can be easily avoided if no undue force is used at the time of passing the first probe.

False passage leads to œdema of the parts and very rarely to cellulitis.

(ii) Hæmorrhage of any severity is very rare. I have seen it once and it was easily stopped by a pressure-pad and bandage.

(iii) Failure to pass the probe. This happened in only one case in which it was found subsequently while doing excision of the sac, that the bony growth was so great that there was osseous occlusion of the lower lacrimal passage.

(5) *Dacryocysto-rhinostomy* (as practised by Toti and modified by Dupuy Dutemps).

This operation is more radical and better results are claimed by the supporters. The only disadvantage about it is that it takes a very long time and perhaps it may be found difficult for those ophthalmic surgeons who have no practice of general surgery.

So far I have done this operation twice and the result was complete cure without any complication in both cases.

Dupuy Dutemps has published the results of 1,000 operations in *Annales Occulistique* of May 1933. His statistics show complete cure in 948 cases, partial failure in 24 and total failure in 28.

I will give a brief outline of the operation.

Preparation of the patient

Half an hour before the operation the mucous membrane of the nose is anæsthetized by passing about four probes with pledgets of cotton at the end and soaked in the five per cent cocaine solution. The probes are kept in the nose for fifteen minutes.

The skin over the lacrimal region is sterilized by the application of tincture iodine rectificatus.

The sac is washed and anæsthetized by putting a few drops of cocaine adrenaline solution in the sac.

The area of the operation is anæsthetized by infiltration anæsthesia using two per cent novocaine solution with a little adrenaline.

Operation

Incision.—A slightly curved incision is made about 13 millimetres internal to the inner canthus. The incision should be so designed, that one-fourth of it is above the internal palpebral ligament and three-fourths below it. The incision goes right down to the bone. By careful dissection the lacrimal sac is exposed and it is carefully detached from the lacrimal fossa, taking care that it is not opened. The adjacent part of the bony outer wall of the nose is exposed and, with an elevator, the periosteum is pushed aside.

The next step is to make an opening in the bony outer wall of the nose. With a special

THE RATE OF DEVELOPMENT OF HOOKWORM EGGS

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
(From the Helminthology Research Laboratory,
Endowment Fund, School of Tropical Medicine,
Calcutta)

THE object of this note is to impress on workers in the tropics the need of recognizing that hookworm eggs undergo comparatively rapid development in an ordinary stool. This is no doubt quite well known to the majority of persons examining stools for hookworm eggs as

(Continued from previous column)

chisel and mallet, the bone is chiselled out and removed. The soft velvety reddish-looking mucous membrane of the nose is exposed. The opening in the bone can be enlarged by a special punch-foreeps.

The next step is to make an incision in the sac and a corresponding incision in the nasal mucous membrane.

Then the posterior lip of the nasal incision is sutured to the posterior lip of the sac incision; for this purpose two needles (Dechamp's and Reverdin's) are used.

The posterior lip of the incision in the nasal mucous membrane is seized with a suitable forceps and the Dechamp's needle armed with fine catgut is passed through the flap. When the needle is well out, one end of the suture is drawn out with a forceps; in this way about three sutures are passed. Then the Reverdin's needle is passed through the posterior lip of the sac incision and the loose end of the catgut suture is tucked in the needle and drawn through the sac flap. In this way all sutures are drawn through the sac lip. This unites the posterior lips of both the parts.

Similarly three or four sutures are passed through the anterior lips.

Sutures are tied and cut short and a two per cent mercuricchrome solution is applied.

The skin incision is sutured with silk or silk-worm gut.

A pad and bandage are applied and the patient allowed to go home.

After-treatment

After-treatment is practically nil, the dressings are changed on the fourth day and again on the eighth day after the operation, when the superficial sutures are removed.

The cure is complete in the majority of cases. If it is found that the passage between the sac and the nasal mucous membrane is not free a Weber's knife is passed through the slit punctum and then through the passage made by the operation.

Suppuration or any other complication is unknown provided thorough asepsis has been observed.

a routine, and these observations will accordingly be considered superfluous by many, but after several years of teaching at the Calcutta School of Tropical Medicine the writer considers this fact well worth emphasizing, because it is surprising how many students who have had considerable experience will maintain that an egg cannot be of hookworm origin if it contains more than four cells—the old textbook description. As a matter of personal experience it is the exception to find hookworm eggs to contain only four cells in stools examined in my laboratory.

Camera lucida drawings of the principal stages of development of hookworm eggs.

The following observations were made on stools passed by patients in the Carmichael Hospital for Tropical Diseases, where the time they were passed was noted so that the actual amount of time before they were examined could be accurately determined. It is felt that giving the exact time in this way will impress the rate of egg development on readers more forcibly than vague references to the space of time involved.

The work was carried out in April and May when the weather is hot; probably at a colder time of the year the development of eggs would be not quite so rapid, but in the average tropical climate without great seasonal temperature variations, this factor would not have a very marked influence.

The complete stools were sent to the laboratory and a sample taken and placed in a 'D. C. F.' tube. No special precautions were taken to scrape off the surface of the stool where the development of eggs would be most rapid, but a portion of feces was picked up on a small spatula plunged deeply into it so that most of the eggs must have come from well below the surface.

An ordinary D. C. F. preparation, using saturated salt solution, was made and this was immediately washed off into water to prevent the strong salt acting on the eggs and probably

killing them. The eggs so obtained were placed on a slide under a coverslip which was ringed with vaseline to prevent evaporation and to permit of examination from time to time over a prolonged period. A few control observations were made with some of the stools, using sugar solution as well as salt. This was done to ascertain if the short time that the eggs were in saturated salt solution had any effect through the exertion of osmotic pressure, as this does not operate in the case of sugar. There was no apparent difference in the early development of eggs which had been collected by salt or sugar solutions so it is probable that for the short time it was in contact with the eggs the salt solution had no deleterious influence.

As a means of readily understanding the rate of development of eggs the following stages have been arbitrarily chosen and each stage has been given a numerical value. The principal stages are also shown in the accompanying figure.

1. Morula with 4 cells.
2. Morula with 6 to 10 cells.
3. Morula with 12 to 16 cells.
4. Morula with 16 to 24 cells.
5. Morula with 32 or more cells.
6. Mulberry, stage A.
7. Mulberry, stage B.
8. Kidney-shaped embryo.
9. Tadpole-shaped embryo.
10. Fully developed embryo in egg.
11. Embryo hatched out of egg.

It will be noticed in the table that the numbers of eggs recorded in the various observations are variable; this is because the numbers of eggs collected from different stools varied considerably, and after this they were washed into small tubes in water and then as many as possible were drawn up in a pipette and transferred to a slide.

It will be seen that 21 stools from five individuals were examined and that only a small proportion of the eggs recovered showed as few as four cells. The actual percentage in both the first and second series of examinations was only between eleven and twelve per cent of all the eggs seen. In one instance two apparently fully embryonated eggs were found in just over five hours after the stool was passed, and in another instance six larvae were found hatched out in a slide preparation that had been put up and ringed with vaseline three hours previously, the stool having been passed for ten hours, when the free larvae were seen. On the whole, development appeared to be somewhat more rapid in eggs that had been removed from the stool by D. C. F. and then left in water, than it was in eggs left in stools. It was also noted that the development of eggs from day to day in stools from the same patient showed great variation in rate, but as far as this investigation went there was no indication as to the cause of this.

(Continued at foot of page 371)

EWING'S SARCOMA

A CLINICAL AND PATHOLOGICAL STUDY OF A CASE

By AMAR NATH GOYLE, M.B., B.S., PH.D.
V. VASUDEVAN, M.B., B.S.

and

K. G. KRISHNASWAMY, M.B., B.S.

(From the Department of Pathology, Medical College
Madras)

THOUGH there are probably some references to this type of neoplastic growth in the older literature, it was only in the year 1920 that Ewing separated it from the general mass of malignant tumours of bone, on the basis of morphology and arrangement of the proliferating cells. The tumour has been called by various names: endothelial myeloma, Ewing's tumour, diffuse endothelial myeloma. Since Ewing's original description, Connor (1926), Codman (1926) and Kolodony (1927) have collected, described and reviewed many cases of this nature and have established this condition as a distinct clinical and pathological entity. That Ewing's sarcoma is by no means a rare condition is shown in a recent review of cases from Johns Hopkins Hospital, in which it formed 15 per cent of all the malignant bone tumours (Geschickter and Copeland, 1931).

Recently we had to report on a specimen removed at the General Hospital by Lieutenant-Colonel K. G. Pandalai, M.S., from a growth of the thigh. This was diagnosed as Ewing's sarcoma by us and it forms the basis of this paper and affords an opportunity for discussing tumours of this nature which as far as we are aware have not been reported in India before.

*Report of case**Clinical history*

The patient, a Hindu male, aged 35 years, was admitted into the General Hospital, Madras, on 11th November, 1934. His chief complaint was a painful swelling in the left thigh. He first noticed it as a small lump which gradually increased in size. The pain had also increased and at the time of admission was continuous, with exacerbations.

Physical examination

There was a soft, tender swelling on the anterior aspect of the middle third of the left thigh. There was no definite margin so that the growth tended to merge imperceptibly into the surrounding healthy tissue. It was hot to touch and the overlying skin was not freely movable. The swelling could not be moved freely in the transverse direction and in the longitudinal direction it could not be moved at all. The inguinal glands were neither enlarged nor tender. The knee joint could not be completely flexed.

(Continued from page 369)

It seems clear from this investigation that a large number of cells in an egg or even the presence of a fully developed embryo is not incompatible with hookworm infection even when stools have only been passed a few hours, especially in the warm weather.

There was a slight fever during his stay in the hospital.

Blood examination was as follows. Total number of leucocytes 9980 per cmm, of which the polymorphonuclear leucocytes were 80 per cent, monocytes 8 per cent and lymphocytes 12 per cent.

A roentgenogram of the left femur taken on 12th November, 1934, showed a distinct widening of the marrow cavity in the middle third of the shaft from destruction of the bone by the growing tumour. There was also a slight expansion of the shaft at the site of the tumour with a slight degree of periosteal reaction. The separation of the cortical part of the bone into longitudinal lamellae is clearly seen in the x-ray photograph (figure 1). The most frequent site of metastases being the lungs—these were x-rayed but did not show any deposits.

Fig 1—Roentgenogram of the shaft of the left femur taken before treatment. Note the widening of the medullary cavity and areas of rarefaction in the cortical bone with some periosteal reaction.

The growth was treated with a radium pad (40 mgm) on 23rd November 1934, which was removed on 14th December, 1934. The total dose given was 20,160 mgm. hours.

Another radiogram (figure 2) was taken on 7th December, 1934, after a course of irradiation and this showed a marked sclerosis both in the shaft and periosteal region at the site of the original tumour, and the honeycombed appearance of the bone was no longer visible.

Fig. 2.—Roentgenogram after irradiation shows marked sclerosis of the shaft and periosteal region.

Naked-eye examination.

The small piece of tissue sent to us was greyish white in colour and of a very soft consistency.

Microscopic examination.

Tissues for microscopic sections were fixed in 10 per cent formalin and in Zenker's fluid and these were embedded in paraffin. Sections were stained with Ehrlich's haematoxylin and eosin, by Leishman's stain, van Gieson's method, and Foot's silver impregnation method. The oxydase reaction was used to determine the presence of the granules in the cells.

A section of the tissue under low power showed a more or less diffuse mass of relatively large cells closely packed together (figure 3). There was no trace of the normal structure of the bone marrow. Here and there were seen round or oval clear spaces containing small collections of cells. Large areas of necrosis were seen in the section and there were also other areas where the cells appeared to have undergone a sort of hyaline or hydropic degeneration. Strands of pink staining hyaline tissue were seen to traverse the section and enclose islands of tumour cells but these, on examination under the high power of the microscope, turned out to be the walls of the blood vessels, many of them containing red cells. There was no trace of osseous or osteoid tissue anywhere in the section.

Under the high power (figure 4) the most predominant type of cell was a moderately large, mostly spherical sometimes irregularly polyhedral cell showing coarse cytoplasmic processes which in less dense sections were seen to intercommunicate with one another. The cytoplasm was scanty, stained very lightly with eosin

Fig. 3.—Note the diffuse collection of cells. The clear spaces containing groups of cells are scattered throughout the section.

Fig. 4.—Same under high power. The cells are large polyhedral with coarse cytoplasmic processes. The cytoplasm is scanty and vacuolated. Note the hyperchromatic nuclei and a few cells in mitosis and one giant cell in the centre. The intercellular substance is absent.

and was vacuolated giving rise to a reticulated appearance. The outlines of the cells were irregular. The nucleus was relatively large oval, spherical or slightly elongated. Many of the nuclei were hyperchromatic and vesicular with a distinct nuclear membrane and showed scattered granules of chromatin. The cells bore some morphological resemblance to reticular cells. Cells with uniformly dense nuclei were also common. Some of the vesicular nuclei showed an indentation on

one side, and nuclei showing mitotic figures were abundant. There was a considerable variation in size, shape and staining reactions of the nuclei though the cells were more or less uniform in size. A noteworthy feature was the absence of intercellular substance. No characteristic arrangement of the proliferating cells was observed and they were diffusely scattered all over the section.

On a closer examination of the clear spaces under the high power, they were found to be devoid of any definite endothelial lining and they contained a number of the tumour cells along with other types of cells. Some of the cells seen in the clear spaces were small, round with a moderate amount of strongly eosinophilic cytoplasm and dense round nuclei resembling normoblasts. Cells of this description were also seen scattered elsewhere in the section. Besides these cells, there were a few giant cells which were both mononucleated and multinucleated, the latter were of the megakaryocytic type with vesicular nuclei. Plasma cells, small lymphocytes, eosinophilic cells and polymorphonuclear cells were altogether absent.

Sections impregnated with silver by Foot's method failed to reveal the presence of reticular fibres. Van Gieson's method did not show any collagen fibres except in the walls of the blood vessels. Frozen sections stained with Sudan III showed numerous fat globules of varying size in the tumour cells.

Blood vessels were abundant and well developed. The clear spaces containing tumour cells and also nucleated red cells as described above may possibly represent blood vessels of an embryonic type.

Diagnosis.—Ewing's sarcoma.

Comment.—The clinical features, namely the intermittent pain which later became continuous, the low fever and the typical skiagram with rarefaction and the site of the tumour (middle of the shaft of the femur) and the response to radium therapy, are all very suggestive of Ewing's sarcoma.

Ewing's sarcoma is a disease of early life. Of 65 Ewing's sarcomata in the material collected by Geschickter and Copeland, 58 cases were observed in patients of the age between 4½ and 25 years and only one case after the age of 40. The oldest person whose age was reported in this series was a woman aged 44. Connor has however reported a case in a patient aged 60. The age of our patient was 35 years. Multiple myeloma however occurs in the fourth and fifth decades of life.

Though a history of trauma is generally available we failed to elicit any such information from our patient.

The intermittent pain following trauma with signs of inflammation simulate closely the clinical symptoms of osteomyelitis of a sub-acute nature.

Ewing's sarcoma differs greatly from other common bone tumours in its location. The site of predilection in the case of Ewing's sarcoma is the shaft and not the end of long bones as is the case with osteogenic sarcoma. The giant cell tumour occurs usually in the epiphysis and multiple myeloma in the flat bones.

Histologically, the present case can be readily distinguished from inflammatory conditions, such as osteomyelitis, syphilis and tuberculosis of the bones. The uniformity of cytology and the absence of osteogenesis and intercellular

material separates it from osteogenic sarcoma. There are good reasons for not regarding this case as multiple myeloma. In the first instance, it is single. The neoplastic cells are not of a myeloid nature as shown by the oxydase reaction nor do they resemble lymphoid cells. A noteworthy feature is the absence of Bence-Jones' proteins in the urine.

Histogenesis.—We may now consider the question of the nature and origin of the proliferating cells in this case. It is difficult to trace the origin of the neoplastic cells in the absence of an opportunity to study the earlier stages of the neoplastic process. But in one or two of the cases in the Registry of Bone Sarcoma of the American College of Surgeons minute foci of tumour cells were seen to be arranged perivascularly in the Haversian canals and it was suggested that these arose from the adventitial cells (Kolodony, 1927). It was, however, not clear whether the cells originated in that situation or were brought there by lymphatics. Ewing (1924) assigned the cells of this tumour to some endothelial category and remarked: '...it may be that the interpretation of endothelium may have to be widened to include this group. I do not think they arise from blood or vascular endothelium. They may possibly arise from the perivascular lymphatic endothelium'. Connor (1926) suggested that the cells originated from the reticulo-endothelial system. As adventitial cells form part of this system this view is in conformity with that of Kolodony. Morphologically, the cells resemble the reticular cells, but a great many of them lacked their typical structure. As a rule, the reticular cells are more elongated with an abundant cytoplasm showing engulfed particles such as erythrocytes, degenerated cells, etc., but in this case the cells are more spherical and the cytoplasm which is small in amount does not show any evidence of phagocytic activity. Moreover, under normal conditions, most of the cells are intimately connected with reticular fibres. We have already pointed out the absence of argentophil fibres. All these variations from the normal structure of the reticular cell can be explained if it is assumed that the proliferating cells are embryonic in type. A cell has two main functions, those of growth and work, and it is well known that the cells of malignant growths lose their physiological function and devote themselves entirely to growth. That the cells of the tumour in the present case are malignant and embryonic in character is indicated by the extreme variation in size and shape and hyperchromatism of the nuclei which also show abundant mitosis and the relatively small amount of cytoplasm compared with the nucleus; also the phagocytic activity and production of reticular fibres representing as they do the physiological activity of the cell it is not unreasonable to assume that they are inhibited by the growth activity. The tendency

to the formation of spindle cells is also not a very prominent feature and may be explained in a similar way, that is to say there is no differentiation of the proliferating cells into other cell types. In the more differentiated type of reticular cell sarcoma, it is common to find an increased amount of reticular fibres and spindle cells.

The presence of fat globules in the cells possibly indicates a degenerative change in the cytoplasm.

The cell characters bear a superficial resemblance to the large lymphocytes. The outlines of the neoplastic cells in this case are however more irregular than those of the lymphocytes and the cytoplasm is reticulated.

The term endothelioma as applied to Ewing's sarcoma is misleading and has led to great confusion in the past. The term endothelioma should preferably be restricted to those tumours the cells of which originate from the true vascular endothelium and show more or less well-developed angioblastic properties. The reticular cells differ fundamentally in their nature and developmental potencies from those of true vascular endothelium. For this reason we consider the term endothelioma unsatisfactory and as we are inclined to believe that the tumour arises from the reticular cells it would be preferable to call it '*reticulum cell sarcoma*'. Geschickter and Copeland were unable to discover any histological resemblance between Ewing's sarcoma and the endotheliomas in their collection and they came to the conclusion 'that osteolytic endothelial myeloma of Ewing was neither primarily osteolytic nor medullary nor endothelial'. One is not surprised at this lack of similarity as the histogenesis and the cytology of the two conditions are different; for in the case of endothelioma the proliferating cells are those of vascular endothelium with angioblastic properties, whereas in Ewing's sarcoma they are reticular cells. If on the other hand one compares Ewing's sarcoma with tumours of reticular origin of other tissues, e.g., lymph nodes, the similarity between the two conditions is at once obvious. From the clinical standpoint also we may mention that true endotheliomas do not respond to irradiation which is in marked contrast to the extreme sensitiveness of Ewing's tumour. Indeed this feature is so characteristic that Ewing used it originally to differentiate it from other malignant tumours of bone.

Codman's view that the tumour is an undifferentiated form of osteogenic sarcoma is not generally accepted for various reasons. Osteogenic sarcoma is, as a rule, highly malignant, and the more embryonic tumour of this nature would naturally be much more rapidly fatal. But Ewing's tumour progresses comparatively slowly. It also differs from osteogenic sarcoma in certain other clinical features such as fever, the slow intermittent onset, the site of origin,

and the high incidence of secondary growth in the bones and the rapid initial response to irradiation. Considering the morphology of the cells and their marked osteolytic properties it is difficult to attribute the origin of this tumour to the osteoblasts.

Site of origin.—The question whether the tumour arises primarily in the bone marrow or in the subperiosteum or endosteum has been discussed at great length by Geschickter and Copeland (1931). According to these writers the elliptical area of shaft involvement with the bulk of the tumour lying subperiosteally is unlike the medullary tumours which are centrally situated and are of spherical contour. This elliptical involvement as seen in a skiagram can be explained as being due to a central tumour absorbing the bone, and displacing the weakened shaft outwards with simultaneous formation of new bone by the periosteum and it is conceivable that if x-ray pictures were taken in the early stages of Ewing's tumour one would find central spherical shadows without any elliptical involvement of bone indicating medullary origin. They also deny that there is early destruction of bone with a widening of the medullary cavity and that fractures are common. But other authors, Ewing for example, regard these occurrences as common. In the present case the x-ray picture shows evidence of expansion of the marrow cavity and the honeycombing of the shaft pointing to the osteolytic nature of the tumour. It is no doubt true that Bence-Jones' protein is usually found in cases of medullary tumours but much importance cannot be attached to this finding. The facts at our disposal do not enable us to point out conclusively the exact site of origin of this tumour. But we are inclined to believe that the tumour arises probably from the reticular cells, and as these cells are present both in the medulla and the cortex there is no reason why it should not arise in both these situations. It would thus be possible to reconcile the divergence of opinion as to the site of origin of the tumour as some of the tumours might arise from the medulla and the others in the cortex from the endosteum or periosteum.

Summary

A case of Ewing's sarcoma arising from the femur of the left side in a man aged 35 years is described. Though the task of tracing the derivation of the neoplastic cells is difficult it is suggested that they arise from the reticular cells on the basis of their morphological and structural characters. If this view be accepted, reticulum cell sarcoma would undoubtedly be a more suitable designation for tumours of this nature from the standpoint of histogenesis than endothelial myeloma. The question of the exact site of origin of the tumour is also discussed with the conclusion that it may arise in the

CALCINOSIS CUTIS

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
 LIEUTENANT-COLONEL, I.M.S.

and

J. P. BOSE, M.B., F.C.S. (Lond.)
 (From the School of Tropical Medicine, Calcutta)

Introduction

NODULAR formations in the corium due to deposit of lime salts are rather an uncommon form of primary skin lesion, though abnormal deposits of calcium salts in the various tissues of the body secondary to long-standing inflammatory lesions are a frequent occurrence. These are commonly found in old lupus nodules, in arterio-sclerotic patches, in caseous tuberculous nodules and sometimes in chronic lesions following a pyogenic infection, such as calcification of the pleura. Then again, there are many cases of calcification described in the literature, occurring as secondary to fat necrosis, to which reference is made later in this paper.

In this paper, we are more concerned with calcification occurring as a primary lesion in the skin or the subcutaneous tissues. This type of lesion, though of much less frequent occurrence, has nevertheless been described in the literature from time to time and a considerable amount of work has already been done on the subject. The ætiology of this condition, however, still remains obscure. The two cases of primary calcinosis cutis described in the present paper, which came under our observation in the course of a few months, and which presented some features of unusual interest, appear to us to be worthy of record. The result of our investigation showed that, at least in one of the cases, though the defect in calcium metabolism was important in causing the lesions, endocrine disturbance, more particularly a lowered function of the anterior pituitary, also played a not unimportant part in either causing or aggravating the condition.

(Continued from previous page)

medullary as well as the cortical part of the bone. A clinical study of the case including x-ray pictures before and after irradiation is also presented.

We wish to thank Lieut.-Col. K. G. Pandalai, I.M.S., for the clinical notes of this case and Capt. T. W. Barnard, Director, Bernard Institute of Radiology, for the x-ray photographs.

Whether the endocrine disturbance is primary or secondary needs further research.

Historical review

Fred Slare (Becker, 1924) inaugurated the chemical study of 'stones' in the human body, thus differentiating true bone formations from the various calcifications and deposits of specific salts. His observations were confirmed by Boerhaave (Becker, 1924). Prior to their work, any bony or stony mass in the body, regardless of its origin, nature, or location, was called a 'stone', and if it was beneath the skin, it was designated as a skin stone.

The first authentic report of calcinosis of the skin was described by Weber (1878). This condition was associated with scleroderma, and Weber interpreted the condition as a form of gout. In the monograph published by Lewen and Heller (1895) there are descriptions of six cases of calcareous deposits in the skin and subcutaneous tissues. Several similar cases also appear in French and Italian literature under the title 'Profichet's syndrome' (1900). Klotz (1905) made rather extensive studies on the process of pathological calcification. Lhermitte (1910) described a case of generalized subcutaneous calcification of unknown ætiology. Thibierge and Weissenbach (1911) described a case of calcinosis of the skin combined with scleroderma and sclerodactylia. Hunter (1913) also described two similar cases.

Within more recent times, the paper written by Becker on osteosis cutis contains an excellent review on the subject. Weidman and Schaffer (1926) have described in complete detail a case of calcification of the skin including the epidermis, with extensive bone resorption. These authors support Klotz in the hypothesis that 'in the process of calcification, there is a primary fatty metamorphosis of tissues and final calcification comes about through a series of intermediate changes in which soaps figure'. Durham (1928) collected the reports of a large number of cases and described one of his own. He has given an excellent review of the literature and seems to think that the colloidal proteins are likely to play a prominent rôle in the formation of calcinosis of the skin, sometimes with associated scleroderma.

Maloney and Bloom (1931) described in great detail a case of calcinosis cutis which they thought to be of metabolic origin. Steinitz (1931), after a detailed study, suggested classification of the different types of calcinosis according to the probable ætiological factor. Epstein and others (1933) suggested that a sclerodermic condition of the skin is probably a precursor of calcification. Tate and Trumper (1933) described a rather unusual case in which the disease was limited to the scrotum. Paterson Ross (1934) described three cases of hypodermolithiasis in which he associated this condition with impaired peripheral circulation.

Quite recently Wilson (1935) has described a typical case of calcinosis circumscripta, which he thinks may be due to endogenous hypervitaminosis D, caused by an unusually high blood cholesterol, superimposed on an old remittent Raynaud's disease.

Types of calcinosis

Maloney and Bloom, in classifying the different types of calcinosis, have divided them into two main groups, local and general. Among the local cases are included those where lime salts are deposited in the tissues, secondary to long-standing inflammatory conditions and in calcification of tumours such as epithelioma, sebaceous atheroma, dermoid cysts or in lesions such as pseudo-xanthoma elasticum. This group the author has described as a purely local disease not dependent on any general disturbance of the body.

The general form of calcinosis has been subdivided into two groups: (1) the metabolic group, and (2) the metastatic group.

(1) *The metabolic type*.—This is supposed to be caused through some imperfectly understood defect of calcium metabolism. The important point about this type of calcinosis is that there is associated bone destruction. The case of a boy, fourteen years of age, described in great detail by Maloney and Bloom belongs to this type of calcinosis.

Epstein and others described a case illustrating the metabolic type of calcinosis in great detail and have come to the conclusion that, in this type of case, the histological changes indicate that the calcification takes place in the collagenous fibres of the corium and in the subcutaneous tissue.

Steinitz who made an extensive review of the literature has further subdivided this metabolic group of cases into the following two distinct types: (a) calcinosis circumscripta, and (b) calcinosis universalis. The former group is characterized by slowly-growing circumscribed deposits of lime salts which commence as small nodules and grow to about the size of a small pea. The overlying epidermis becomes thin and ruptures, the calcareous mass is extruded and healing occurs. The lesions are usually multiple and are commonly situated on the hands, the extensor surface of the elbows and knees, and rarely on the trunk. Apart from mechanical interference with joint movements, the disease does not constitute any serious disability and usually there is no danger to life.

In the other group, i.e., calcinosis universalis, the calcareous deposits occur as large plaques and masses in the skin and subcutaneous tissues and frequently in the connective tissue of the fascia, nerve sheaths and muscles. In some cases, there has been widespread calcification throughout the vascular system. Durham has described a case in which there was a large calcareous mass in the myocardium. When the

calcareous masses disintegrate, there is often severe ulceration with secondary infection and the disease may end fatally.

(2) *The metastatic type*.—In this condition, the blood calcium is markedly high and is almost invariably associated with bone disease such as osteomyelitis, caries or lymphatic leukemia. A detailed description of a case of this type has been given by Weidman and Schaffer. In the case described by them, the calcification of the skin was not limited to the epidermis, but extended widely throughout the corium involving the sweat ducts and glands, pacinian corpuscles and nerve trunks. This the authors regard as an expression of calcareous metastasis because there was definite resorption of the bones in several parts of the skeleton. Morse (1921) also described an interesting case belonging to this group in which the subcutaneous tissue of an infant became calcified.

It will be at once evident that this type differs materially from the metabolic type of calcinosis cutis.

Ætiology

The ætiology of calcinosis is obscure and probably differs in the different types of cases described above. In the metabolic type it has been suggested that it is due to an error of calcium metabolism and is probably analogous to gout, the lesions being of the nature of calcium tophi. In the metastatic group, associated with extensive bone disease, it seems probable that the calcium comes from the bones via the blood stream to the skin, where it is deposited, probably as an attempt at excretion.

The association between calcinosis and scleroderma has been emphasized by several writers. The first attention to this association was probably drawn by Weber and then by Lewen and Heller. Hunter described two cases and collected two others in English literature and eight more from European literature. Durham collected the reports of thirteen such cases and described a case of his own in great detail. Langmead (1923) is definitely of opinion that scleroderma, dermatomyositis, fibrosa and calcinosis are manifestations of the same pathological process, the nature of which is unknown. Epstein and others, making detailed histological studies in a case of calcinosis of metabolic origin, thought that the frequent association of diffuse scleroderma probably indicates a common ætiology and suggests that the sclerodermic process is preparatory to calcification.

Davis (1912) has drawn attention to subcutaneous calcareous concretions in Raynaud's disease. Very recently Paterson Ross has described three cases of hypodermolithiasis in which he associates the condition with the impairment of the peripheral circulation. He suggests that in the early stages the progress of

the disease may be arrested by sympathetic ganglionectomy.

The association of calcification with fat atrophy has been mentioned by Kuznitsky and Melchior (1916). These authors described a case in which there were extensive calcareous deposits in the skin. This was thought to be the result of universal fat atrophy—a typical lipodystrophia progressiva. Morse described a case of extensive calcification of the skin and subcutaneous tissue occurring in areas of fat necrosis in a child 3½ years old. Klotz believes that in such conditions the calcium is first laid down as soap, later changing into less-soluble carbonate or phosphate. It has been mentioned in the literature that there are certain systemic conditions which enhance the local deposition of calcium. Amongst these factors may be mentioned the pH of the blood, the action of sunlight, and the ingestion of vitamin D. The work done by Barr (1930) on this subject deserves special mention here.

What part endocrine disturbance plays in the ætiology of this condition is not known at present, though vague reference to it has been made in the literature. Durham questioned the function of the thyroid and the parathyroid glands. The case described by Maloney and Bloom 'showed signs of endocrine disturbance', though the authors made no further comments on it.

It will be seen from a study of the above review that, although an enormous amount of work has been done and various theories put forward, the real ætiological factor of the disease is still far from being understood. Our contention is that, at least in one of the cases investigated by us, we got some evidence of dysfunction of the pituitary gland and treatment on that basis had the desired effect, and we trust that further work on the same lines may throw more light on the still obscure ætiology of primary calcinosis cutis.

Cases

Case I.—Mrs. L. W., an Anglo-Indian female, aged 27; admitted into hospital on 9th May, 1934.

General appearance.—Marked spinal curvature of kypho-scoliotic type; no noticeable developmental defects; lower extremities somewhat shorter in proportion to the rest of the body; prominent malar bones, large square jaw, features somewhat heavy, skin rough and thick; voice deep.

Cutaneous lesions.—Fairly numerous bony-hard nodules situated in the dermis varying in size from a pea to a small areca nut but distributed symmetrically, mostly in the vicinity of the extensor aspects of the joints, namely the ankles, the knees, the wrists and the elbows. The nodules were raised above the surface of the skin, which, owing to stretching, was pale and yellowish over these nodules. Except for one nodule on the spine and another on the shoulder, the trunk was unaffected. The large nodules were irregular in outline. Several pitted areas were present along the extensor and flexor aspects of the arms and legs. There were no subjective symptoms, except for tenderness or deep pressure. Duration about 10 years.

Each nodule began as a small pimple or papule, slightly raised above the level of the skin and grew

very slowly till, in the course of a couple of years or more, the largest nodules began to soften and ultimately burst through the skin, discharging the gritty cheesy contents. Resolution was very often accompanied with low remittent fever. Healing of these broken-down lesions was uninterrupted.

The patient had symptoms of dysentery off and on for the last ten years, and for the last few years had developed epigastric pain and sickness soon after taking her meals. She had been treated on three previous occasions as a case of sporotrichosis with fairly heavy doses of potassium iodide, with good results.

Physical examination showed nothing abnormal.

Case I

Electrocardiogram.—Slight arrhythmia of sinus origin.

Laboratory examinations. Blood.—No agglutinins against typhoid, para A and para B. Aldehyde and antimony tests—negative (diluted 1/10). Wassermann reaction—negative.

Stool.—Protozoa nil. Scanty trichuris eggs present. *Bact. metadysenteriae* isolated once only.

Contents of nodules on chemical examination showed presence of calcium in fairly large amounts. No cholesterol was detected.

The skiagram showed a large number of calcified nodules all over the body, most numerous on the extremities and near the joints; a very large linear deposit was seen on the inner aspect of the left thigh, extending from the knee to about the middle third of the thigh. The heart and lungs were found normal.

The patient was re-examined after six months. Her condition remained unchanged and she had a number of nodules under the skin. She said that as long as she

Section I (case I) (low power).—Entire section of the calcified mass, showing the position of the deposit, which is in the deeper part of the corium just above the superficial fascia. The entire deposit is divided into several small masses of various shapes each being surrounded by a capsule and gives a loculated appearance.

Section II (case I) (high power).—Shows deposit of calcium with a fibrous capsule. A few giant cells are seen at the periphery of the deposit.

used sodium phosphate no fresh nodules appeared, but when she stopped the drug, fresh deposits occurred. Otherwise she felt fairly fit.

Case II.—A. M., a Hindu female, aged 8 years, admitted to hospital on 14th November, 1934.

General appearance.—The stature of the child was out of the ordinary, head unusually large and face of the masculine type; arms and legs abnormally long; prominent malar bones; large square lower jaw; tongue rather large; features heavy; teeth widely separated from one another.

The previous history of the child is interesting. For some years past, she had been increasing in weight and in stature disproportionately to her age and the condition was then diagnosed as a pseudo-hypertrophic muscular paralysis; the child was unable to climb stairs owing to weakness in the muscles; treatment was of little avail.

Cutaneous lesions.—These began three to four years ago. Small hard nodules under the skin varying in size from that of a pin head to a pea. Distribution more or less even, mostly in the vicinity of the extensor surfaces and near joints, mainly knees, wrists, and elbows. The skin over the nodules was movable. A hard cord-like swelling in which a few separate very hard nodules could be felt were present in the thigh and the leg, both on the extensor surfaces. Some of these tumours burst spontaneously and a whitish creamy material came out leaving an ulcer, which took a long time to heal. On chemical examination, this material proved to be composed mainly of calcium carbonate and partly of calcium phosphate. No cholesterol or fatty acids could be detected. Culture showed streptococci and staphylococci.

Blood chemistry.—A glucose tolerance test showed a definite marked increase in the tolerance. Blood cholesterol normal. Blood N-P N., urea, uric acid, sugar, all were within normal limits. Blood calcium was 14 mgm. per 100 c.cm. on admission.

Histological findings.—In the epidermis, the nuclei of the prickle cells look vacuolated with nuclear material represented as a thin demilune towards the periphery. Here and there almost all the cells of the prickle cell layer are of cylindroid appearance and show melanin pigment. The horny layer is normal. In the corium there is papillary and sub-papillary œdema without any evidence of infiltration. There is a slight perivascular and perilymphatic infiltration; but no evidence of inflammatory changes in other parts of the corium. The sebaceous and sweat glands are partly atrophied. Lime salts are seen deposited deep down in the corium. The blood vessels in the deeper portion of the corium show endarteritis obliterans and a condition of thrombo-angiitis. The deepest portion of corium shows a fair number of newly-formed arterioles with walls consisting of a single layer of endothelial cells and all showing thrombo-angiitis. This portion of the corium shows a distinct area of patchy extravasation.

The deposit itself appears to be distributed in small loculi in the connective tissue elements the walls of which are formed by proliferation of connective tissue cells and fibroblasts. A large number of swollen and disintegrating connective tissue cells can be seen in the calcifying debris.

Treatment

It is to be expected that in a disease where so much diversity of opinion exists regarding the aetiological factor, the suggestions regarding treatment would naturally be diverse. That this is so can readily be seen from a study of the literature. As a matter of fact some authors, who have described the other aspects of the disease in great detail, preferred to remain silent regarding any suggestions as to the line of treatment to follow. The treatment of calcinosis cutis therefore continues to be unsatisfactory.

Among the lines of treatment suggested may be mentioned that of Craig and Lyall (1931) who advocated the administration of di-sodium phosphate in doses of 2 grammes three times a day. Kennedy (1932) obtained marked improvement in his patients by the use of a ketogenic diet. Bauer (1931) advocated the

the skin. The results of this mode of treatment have also been uncertain and unconvincing.

Reference to some of the other methods of treatment advocated has already been made under the heading of aetiology.

In both the cases described by us, we administered fairly large doses of sodium phosphate extending over long periods particularly in case I. No noticeable change was observed, though it was found that while the patient was on sodium phosphate no fresh nodules appeared. Parathyroid gr. 1/10 three times a day was tried in case I, with uncertain results. Case II had parathyroid treatment before she came to us, and the result as described to us was that 'the nodules continued to increase in number and size, and the treatment had to be stopped'.

Gradually increasing doses of anterior pituitary extract (with small doses of thyroid, to enhance its action) were tried in this case and within a short time noticeable changes were observed in the nodules; they began to get softer and smaller, and by the time the patient left hospital her condition was much improved. She has been continuing the treatment with very good results.

Discussion

It will be seen from what has been said above that the two cases described by us belong to the group of the metabolic type of calcinosis cutis (calcinosis circumscripta of Steinitz). In addition to the typical clinical picture we have given, these cases appear to present a few unusual features, which we hope will be of special interest to other workers when investigating cases of this type.

Both the cases, and more particularly case II, appeared to present definite physical signs of previous hyperpituitarism. The masculine type of face, enlarged head and long bones, prominent malar bones, a large thick lower jaw, large tongue, coarse thick skin and heavy features, all point to a condition of hyperaction of the anterior lobe of the pituitary, though at the time the patient came under our observation she had drifted towards a condition of hypopituitarism, as is usual: Blair Bell (1919) has stated that patients suffering from acromegaly live for some years in a condition of hyper-hypophyism, but finally drift into a condition of hypo-hypophyism. Cushing holds the same view and states that hypopituitarism very often succeeds hyperpituitarism and it is not uncommon to find at this later stage a cystic or necrotic change in the anterior lobe of the pituitary. Our opinion is that both the cases, specially case II, presented signs and symptoms of hypopituitarism at the time of investigation. The high sugar tolerance in case II is additional evidence in support of this.

There is evidence in the literature that the pars anterior of the pituitary gland exerts a great influence on calcium metabolism and in conditions where the function of this gland is

Case II

use of a diet low in calcium combined with a decalcifying agent, such as ammonium chloride.

The treatment of the condition with parathyroid gland has been tried by some of the workers, though there are others who are against the idea of administering extracts of parathyroid in this condition. Durham, however, believed that in this condition the parathyroid glands are normal in histological appearance. Hueper (1927) believes that parathyroid hormone helps calcification and that experimental calcification can be produced in animals by injecting parathyroid hormone.

The administration of thyroid in this condition has also been advocated, the idea being that thyroid dysfunction is probably the factor in the accompanying sclerodermic condition of

suddenly lowered, as in the later stages of acromegaly there is a tendency towards calcium retention in the system. Franchini (1907 and 1908) made detailed investigations in several such cases and came to the same conclusion.

It will thus be seen that the anterior pituitary plays some part in the proper utilization of calcium in the system. Klotz (1912) has definitely stated that the administration of the extract of anterior pituitary caused an increased utilization of calcium in the tissues.

We must admit that the therapeutic use of the extract of the anterior lobe of the pituitary made by us with apparent success, in case II, was started with an empirical, if not a speculative idea, as the data we obtained from the clinical signs and symptoms and the laboratory examinations were not complete. Nevertheless, we would emphasize that the line we have indicated is well worth following and we feel that further investigation on similar lines, in similar cases, would throw more light on the hitherto obscure problem of calcinosis cutis.

Summary and conclusions

(1) Two typical cases of the metabolic type of calcinosis cutis (calcinosis circumscripta) have been studied and described. The histological changes indicate that calcification took place in the collagenous fibres of the corium and in the subcutaneous tissues.

(2) A possible lowered function of the *pars anterior* of the pituitary gland as one of the ætiological factors is suggested and treatment of this condition by extract of the anterior pituitary lobe is recommended.

(3) It is suggested that investigation on the lines recommended may throw more light on the ætiology of the disease.

EVIPAN-SODIUM

(INTRAVENOUS ANÆSTHETIC)

By P. N. BANERJEE, M.B.

Anæsthetist, Mayo Hospital, Calcutta

EVIPAN-SODIUM is issued in dry ampoules of 1 gramme.

With each powder is also supplied an ampoule containing 10.5 c.cm. of distilled water.

Chemistry.—It is the sodium salt of N-methyl-cyclo-hexenyl-methyl barbituric acid, which dissolves freely in water.

Pharmacology.—It is not a volatile narcotic and as such it is uncontrollable. It is rapidly detoxicated. Detoxication depends on chemical decomposition—oxidation—chiefly in the liver. Traces of unchanged substance are excreted in the urine. The blood pressure drops, both systolic and diastolic, and quickly returns to normal. The pulse rate increases and becomes rapidly normal again, it remains regular and full. Death is always due to cessation of respiration. Metabolism, temperature, blood-urea, blood-sugar, urine, remain unaltered, providing that it has not got any injurious effect on any organ.

Disappearance of corneal reflex and absence of other reflexes represent full anæsthesia.

Pre-operative measures.—Preliminary preparation of the patient for the anæsthetic is not necessary. He need not remain without food on the day of the operation. Pre-operative administration of morphine, scopolamine, or omnopon is unnecessary and I do not use them, so as to avoid cumulative action on the respiratory centre. With preliminary medication I have seen prolonged unconsciousness and found difficulty in ascertaining the proper dosage in

patients who are very drowsy. It would not be out of place to mention here that patients need not be aware of the anæsthetic which is to be used and which they often apprehend more than the operation.

Preparation of the solution.—Draw 10 c.cm. of distilled water in a 10 c.cm. record syringe. Break the neck of the ampoule containing the dry white evipan-sodium powder. Inject the water into the ampoule and dissolve the powder by shaking and repeated aspiration into the syringe. The solution must be freshly prepared.

Contra-indications.—Evipan-sodium should not be used :—

For long operations.

In seriously ill, old and cachectic patients.

In circulatory and respiratory disturbances.

In cases of jaundice and extensive damage to the liver parenchyma.

In eclampsia, diseases of the central nervous system, and general disturbance of metabolism.

Dosage and technique of injection.—The arm is prepared as for an intravenous injection and having everything ready for the operation, the solution is injected into the median basilic vein with ordinary aseptic precautions. The injection must be given very slowly at an average rate of 1 c.cm. in 10 to 15 seconds. The dosage is regulated during the injection by exact observation of the patient and it is here that experience is necessary. The patient is asked to count and it is noted the moment the patient stops counting and falls asleep. If the patient is young and strong, half as much again is injected, i.e., if he stops counting after 4 c.cm. have been injected (induction dose) then a further 2 c.cm. (additional dose) would be required for a short operation. I have found it quite safe to inject a little more than this to ensure complete anæsthesia in healthy average individuals. That is, 4 c.cm. (induction dose) + 2 c.cm. (additional dose) + 1 c.cm. = 7 c.cm. (total dose).

Remarks.—In most cases the patients fall asleep with a long drawn yawn, slight muscular tremors occur, jaw and tongue become relaxed, for a moment there is definite diminution of respiration. This should be carefully watched and much stress must be laid on this. Great care must be taken and a constant watch for a free air-way should be continuously maintained. Respiration soon becomes regular in rhythm. The colour remains fresh and pink.

The operation may be commenced immediately the injection has been given. It is preferable to wait for a minute or two to ensure the anæsthesia becoming deep enough. If too small a dose is given or in some very resistant patients with an average dose, a temporary stage of excitement is observed. This is very unpleasant to the operator and a large amount of general anæsthetic is required to bring such patients properly under. The duration of anæsthesia is on an average 15 to 20 minutes. If it is decided

that the operation will last for more than 20 minutes the addition of inhalation anæsthesia (mostly ether) must be resorted to. This must be started early, before the patient is coming out of evipan-sodium and the transition must be gradual and unnoticed, and if done in this way will require very little anæsthetic. Otherwise the same difficulty will arise, the patient becomes boisterous and requires a large amount of anæsthetic, as in the case of insufficient dosage. No hard-and-fast rule can be laid down for the regulation of the dose of evipan-sodium and the dose varies with individuals. Great care and exact observation is necessary to regulate the proper dose of every patient. It is not necessary to take body weight into consideration as the dose is determined by age, and constitutional behaviour during the injection. Females require a little less than males.

A condition of excitement before the operation is almost always due to under-dosage. During the injection fine tremors run over the whole body and also the occurrence of a tonic rigidity of the skeletal muscles and holding of breath has been observed. It has also been noticed where the dose has been insufficient that the patient though unconscious becomes resistant. Some patients awake within half an hour to an hour and become very boisterous and shout so much that morphia is needed to keep them quiet. Others sleep quietly for a longer period and awake fully refreshed.

No post-operative vomiting has ever been observed.

The chief indication for evipan-sodium is for small operations of short duration but it has been used by me with additional doses in major operations like hernia without any ill effects. In a case of appendicectomy which lasted nearly an hour, a second intravenous injection of 7 c.cm., twenty-five minutes after the first 10 c.cm. (total 17 c.cm.), was given by me with complete and satisfactory anæsthesia. It has also been given by me repeatedly on the same patient.

No incident threatening life nor any serious disturbance occurred in my series. Excepting the fact that the respiration becomes shallow at the beginning of injection, there has been no cause of anxiety in my series of cases during the operation or after the patient was taken to the wards.

The drug should never be used single-handed, as a constant watch for a free air-way should be continuously maintained, so it should always be administered by an anæsthetist who will be able to maintain the free air-way and will always be ready to give a general anæsthetic if necessary. Respiratory failure and circulatory collapse have not been seen in my series of cases and in my opinion these can be prevented by a proper selection, careful watch, correct dose and faultless technique. The drug

(Continued at foot of next page)

A NOTE ON THE RELATIVE VITAMIN C-VALUES OF MILK AND CURD

By A. R. GHOSH

and

B. C. GUHA, Ph.D., D.Sc. (Lond.)

(From the Biochemical Laboratory, Bengal Chemical and Pharmaceutical Works, Ltd., Calcutta)

In this country curd is very extensively consumed especially by the adult population and is very frequently preferred to milk. Accordingly it was considered of interest to investigate how the ascorbic acid content of milk was affected by the process of the conversion of milk into curd. It was conceivable that the warmth needed for curdling would adversely affect the stability of the vitamin in milk. On the other hand, the lowering of pH owing to the formation of acid might stabilize the vitamin. There was also the third possibility that the lactic acid bacillus might be able to synthesize the vitamin, in which case there should be an increase in ascorbic acid content. We have, therefore, investigated the same sample of cow's milk before and after conversion into curd and we have obtained evidence to show that the formation of curd stabilizes the vitamin in milk completely, which would, otherwise, be lost to a certain extent even by storage at 0°C. There occurs, however, no increase in the vitamin C content during the curdling process.

Experimental

The method of estimating ascorbic acid by titration against 2:6—dichlorophenol indophenol, as modified by us (Ghosh and Guha, 1935; Guha and Ghosh, 1934), was employed.

(Continued at foot of next column)

(Continued from previous page)

should only be used by an expert anaesthetist who is able to attend to emergencies and apply restoratives should matters ever become serious. Artificial respiration should be employed, oxygen should always be kept readily available together with coramine and lobeleine.

Patients who had experience of previous inhalation anaesthetics expressed satisfaction with evipan-sodium narcosis. If intravenous methods are preferred it is an excellent anaesthetic for short operations, its action is so rapid and pleasant; it is extremely useful in minor surgery especially where slight reflex movement is not a matter of any great concern.

In my series of 78 cases it was used with success in the following operations:—

Whitlows, opening of abscesses, amputation of fingers, operations on the mammae, hydrocele, setting of fractures, reduction of dislocations, ankylosis, tonsillectomy, enucleation of the eye, linear extraction of cataract, carbuncles, inguinal hernia and appendicectomy.

A NOTE ON THE VITAMIN B₁, B₂- AND C-VALUES OF COUNTRY LIQUOR PREPARED FROM THE DATE

By H. G. BISWAS, M.Sc.

and

B. C. GUHA, Ph.D., D.Sc. (Lond.)

(From the Biochemical Laboratory, Bengal Chemical and Pharmaceutical Works, Ltd., Calcutta)

In countries inhabited by rice-eating people and affected by beri-beri, the consumption of crude liquors prepared from some indigenous trees have often been stated to be of considerable nutritional significance. The diet in such countries is to a large extent one-sided and relatively rich in carbohydrate. The provision of vitamin B₁ in the national dietaries in these countries becomes of considerable importance and the

(Continued from previous column)

Curdling of the milk was effected by seeding with a very small amount of curd and incubating at 35°C. for 24 hours.

The following results were obtained:—

TABLE I

	Ascorbic acid (mg.) per c.cm.
Cow's milk (fresh at room temperature)	0.007
Curd formed from the same sample of milk during 24 hours at 35°C.	0.007

In table II are given the comparative values of the ascorbic acid of a sample of milk after different intervals of storage at 0°C. and also after curd formation at 35°C.

TABLE II

	Ascorbic acid (mg.) per c.cm.
Cow's milk (fresh)	0.010
" (after 3 hours at 0°C.)	0.009
" (after 6 hours at 0°C.)	0.008
" (after 24 hours at 0°C.)	0.007
Curd from the same milk (obtained after 24 hours at 35°C.)	0.010

Summary

(1) There is a gradual but slow loss of ascorbic acid in cow's milk stored at 0°C.

(2) The formation of curd stabilizes the ascorbic acid of cow's milk completely even if the curdling is carried out for 24 hours at 35°C. The curd retains the entire amount of the ascorbic acid of fresh milk.

(3) As there is no increase in the ascorbic acid content during the curdling process, the lactic acid bacillus apparently cannot affect the synthesis of this vitamin under the stated conditions.

country liquors have been stated to supply this need to some degree. It has been reported, for instance, in *Nature* (1934, 2nd March, p. 322) editorially that, 'a short time ago, the island of Nauru in the Pacific suffered from a most alarming outbreak of beri-beri, especially infantile beri-beri: the officials in charge of the island had first of all encouraged the consumption of milled cereals, and then forbidden the consumption of the intoxicating national drink—"toddy"—made from the fermented swathe of the coco-nut. Thus the diet was deficient in vitamin B₁. It is dangerous for authority, with inadequate knowledge of problems of nutrition, to control food policy'.

Country liquor, prepared by the fermentation of a juice obtained by incision into the trunk of the date tree, is extensively consumed in this part of the country, especially during the cold weather. We have investigated the vitamin B₁-, B₂- and C-values of different samples of this liquor and we have found that they are poor in vitamin B₁ but that they contain a certain amount of vitamin B₂. The ascorbic acid value of the liquor, however, is fairly high, being about 10 times that of an average sample of cow's milk in Calcutta (Ghosh and Guha, 1935)^b.

In order to find if fermentation would affect the vitamin content of the liquor, the fresh juice obtained from the date tree was also examined. Although strict comparison is not warranted, as the determinations were not made with the same material, fermented and unfermented, the average values would indicate that the fresh juice contains the same amount of ascorbic acid as the liquor but that it is poorer in vitamin B₂. This might indicate that some vitamin B₂ is produced in the fermentation process, but this observation requires further confirmation. The fresh juice is practically as deficient in vitamin B₁ as the liquor.

Method.—The biological method of assay with young rats was adopted for the estimation of vitamins B₁ and B₂ (Guha and Chakravorty, 1933a) and the titrimetric method was employed for the determination of ascorbic acid (Guha and Ghosh, 1934; Ghosh and Guha, 1935)^a.

Both the liquor and the fresh juice were concentrated under reduced pressure for feeding experiments. The fresh juice and liquor were used as such for ascorbic acid determination. The ascorbic acid content of the liquor was also determined at intervals in order to see whether it deteriorates.

The pH of the fresh juice was usually 4.6 and of the liquor 4. The alcohol content of the liquor varied between 2.6 and 5.4 per cent by volume.

Results.—The fresh juice contained on an average 7 units of vitamin B₂ per 100 c.cm. (as defined by Guha and Chakravorty, 1933b), while the liquor contained 14 units per 100 c.cm.

(Continued at foot of next column)

A REPORT ON PLAGUE IN PEERMADE (TRAVANCORE STATE)

By N. KRISHNAN TAMPI, M.B., B.S., B.S.Sc. (Mad.),
Dr. P.H. (Johns Hopkins)

Medical Officer of Health, Travancore State

Historical introduction

PLAGUE started in Bombay in 1896 and spread rapidly throughout India. It appeared in the Madras Presidency in 1898 and according to Russell (1930) the districts adjacent to Travancore State were soon infected: Coimbatore in 1899, Nilgiris in 1903, Malabar in 1906 and Madura in 1910. The Cumbum valley in Madura which adjoins the Peermade taluk of Travancore was first infected in June 1920 and has remained continuously infected since that date. It is probable that plague entered Travancore by way of neighbouring infected districts in Madras Presidency.

The earliest reference to plague in Travancore is the Government Order issued in 1904 declaring Aramboly, Shencottah and Munambom as plague observation stations. These three are frontier stations guarding the entrance from Tinnevely district and Cochin. The frontier station at Kumili in Peermade taluk was not included in that notification as Madura and Cumbum valley were not infected at that time

(Continued from previous column)

Both the juice and the liquor failed to support growth or even maintenance of weight even in daily doses of 15 c.cm. (previously concentrated *in vacuo*), when supplied as the source of vitamin B₁.

Both the juice and the liquor contained 0.1 mg. ascorbic acid per c.cm. The ascorbic acid content of the liquor on standing at room temperature (27°C.) for 7 hours and for 3 days fell to 0.08 mg. and 0.05 mg. respectively.

Summary

Vitamin B₁-, B₂- and C-values of the country liquor made from the date have been estimated. It is relatively deficient in vitamin B₁, but contains considerable amounts of vitamin B₂. It is about 10 times richer in vitamin C than an average sample of cow's milk in Calcutta.

The vitamin values of the fresh unfermented juice are also of the same order. The fresh juice appears to be somewhat poorer in vitamin B₂ than the liquor.

and the importation of plague through Kumili was not then considered as probable.

In 1910 an imported case of plague from Palghat was reported in Meenachil taluk; in 1920 one death from an imported case of plague was recorded at Chothippara estate in Peermade, the infection being imported from Cumbum valley. There were four attacks and three deaths from plague, all imported cases from Cumbum valley in 1921 in Devicolum taluk. There was one death of an imported plague case from Tuticorin reported from Agasteeswaram taluk in 1924.

The first indigenous cases of plague in Travancore were reported from Devicolum taluk in 1927 and during 1928. There were 13 attacks and 5 deaths in this outbreak. A special plague officer and staff were appointed for the control of this outbreak and mass inoculation, disinfection of goods and coolie lines and rat destruction were undertaken. The administrative control of plague operations was vested in the Commissioner, Devicolum.

In Peermade taluk, the earliest record of indigenous plague was in December 1930 when two deaths from suspected plague were reported. These were not confirmed by microscopical examination. Numerous dead rats were reported from Chittappanpara estate in February 1931; two deaths from plague both indigenous cases, in which diagnosis was confirmed by the bacteriologist, were reported from Kumili early in April 1931 and on 11th April, 1931, Government passed orders declaring Kumili as a plague-infected area.

In April 1932, plague broke out at Bonami estate, Peermade, in a severe form and the infection continued there till the end of May. Cases of human plague were also reported from Cheenthalar and Ladrum estates, in Peermade taluk in July the same year. The plague outbreaks at Bonami, Cheenthalar and Ladrum are considered in more detail in a subsequent section.

General description of Peermade hills

The Peermade taluk forms part of the high-land division of the Travancore State. On the east it touches the Madura and Ramnad districts of the Madras Presidency. The following description of the area is extracted from the *Travancore State Manual*: 'The Peermade hills form an extensive plateau with peaks rising up to 5,000 feet. The land slopes from the High Ranges in Devicolum southwards to the Cardamom hills and Peermade. From the main range and from the western watershed of the Peermade plateau rocky spurs run out to the west and north-west extending at times to within a short distance of the sea forming a series of parallel valleys drained by numerous rivers. The Peermade taluk is divided into five pakuthies or smaller revenue subdivisions, viz, Millappara, Peermade, Peruvanthanam, Periyar

and Vandanmettu. Of these Periyar and Millappara consist of reserve forests which go to make up the catchment area of the Periyar lake. Peruvanthanam pakuthy on the western slope contains most of the rubber estates and Vandanmettu pakuthy on the eastern slope contains most of the Cardamom lands. The chief tea estates are distributed over the central area in Peermade, Periyar and Vandanmettu pakuthies'.

The main highway from Kottayam to Madura district traverses the Peermade taluk from the 33rd to the 70th mile. Numerous roads branch off from this road to the various tea estates, but the Cardamom lands are not accessible by these roads. A plague observation and disinfection station is located at Kumili, at the 70th mile on the main road at the entrance from the Cumbum valley of the Madura district. Numerous bridle paths lead down from the Peermade taluk to the Cumbum valley and at the three most important bridle paths, viz, Chellarcoil, Cumbumettu and Rammakkal, plague observation stations are located, in order to prevent importation of infection from the infected villages in Cumbum valley.

TABLE I

Attacks and deaths from plague in Cumbum valley from the year 1920 A.D.

Year	Attacks	Deaths
1920	Not available	4,098
1921	Do.	544
1922	Do.	241
1923	7,109	3,652
1924	734	385

Population and area

Peermade taluk has an area of 450 square miles and a population of 46,023 (1931 census) against a population of 24,026 according to the census of 1921. This enormous increase in population is due to immigration from the neighbouring districts consequent on the rapid development of the tea and rubber estates during the years after the census of 1921. More than half of this immigrant population come from the districts of Madura, Coimbatore, Malabar, Trichinopoly and Tinnevely all of which include important and well-recognized plague-infected areas.

rainy days being 157. The highest monthly rainfall averaging about 50 inches occurs in June and July during the south-west monsoon. In the north-east monsoon, during the months of October and November, the monthly rainfall averages between 10 and 20 inches. In the dry months from January to March the average monthly rainfall is only 2.5 inches.

The relative humidity varies from 85 per cent to 100 per cent in the periods from June to August, while from January to March it is around 75 per cent. The monthly maximum temperatures vary from 70°F. to 80°F. while the mean monthly minimum temperatures vary from 53°F. to 65°F. The monthly maximum and minimum temperatures as well as relative humidity for the Bonami estate (where the plague outbreak occurred in 1932) for the years 1931 and 1932 are shown in table III. The observations with regard to the meteorological conditions in Peermade show that the climate there is favourable for the multiplication of the rat-flea *X. cheopis* which is the reputed transmitter of plague. Hirst (1927) says that a mean temperature of 75°F. with a fair amount of moisture in the atmosphere favours *cheopis* breeding and this leads to an increased *cheopis* index and to rat and human plague. Above 80°F. *cheopis* breeding is checked. It is also stated that plague does not maintain itself in epidemic form when the mean temperature is above 80°F. or when it falls below 68°F. In Bonami estate in Peermade where an outbreak of plague occurred in 1932 the monthly mean temperature was between 74.65°F. and 62.25°F.

TABLE III

Temperature and relative humidity observed at Bonami during 1931 and 1932

Climate

Peermade has a cool moist climate. The average annual rainfall recorded at the Peermade Residency for the last 58 years is 205.30 inches which is the highest record for any station in Travancore; the average number of

In view of this information the temperature conditions in Peermade taluk from February to May can be considered as favourable for the existence of plague in epidemic form, while during the other months it is not sufficiently low to prevent outbreaks.

Rats and rat fleas

In Peermade the opportunities are numerous for close association between rats and man. The houses are crowded together, dark and ill-ventilated. The holes in the floor and the ceiling offer excellent shelter for rats. The coolie lines are insanitary and overcrowded and the tea bushes around the lines also offer good shelter for the rats.

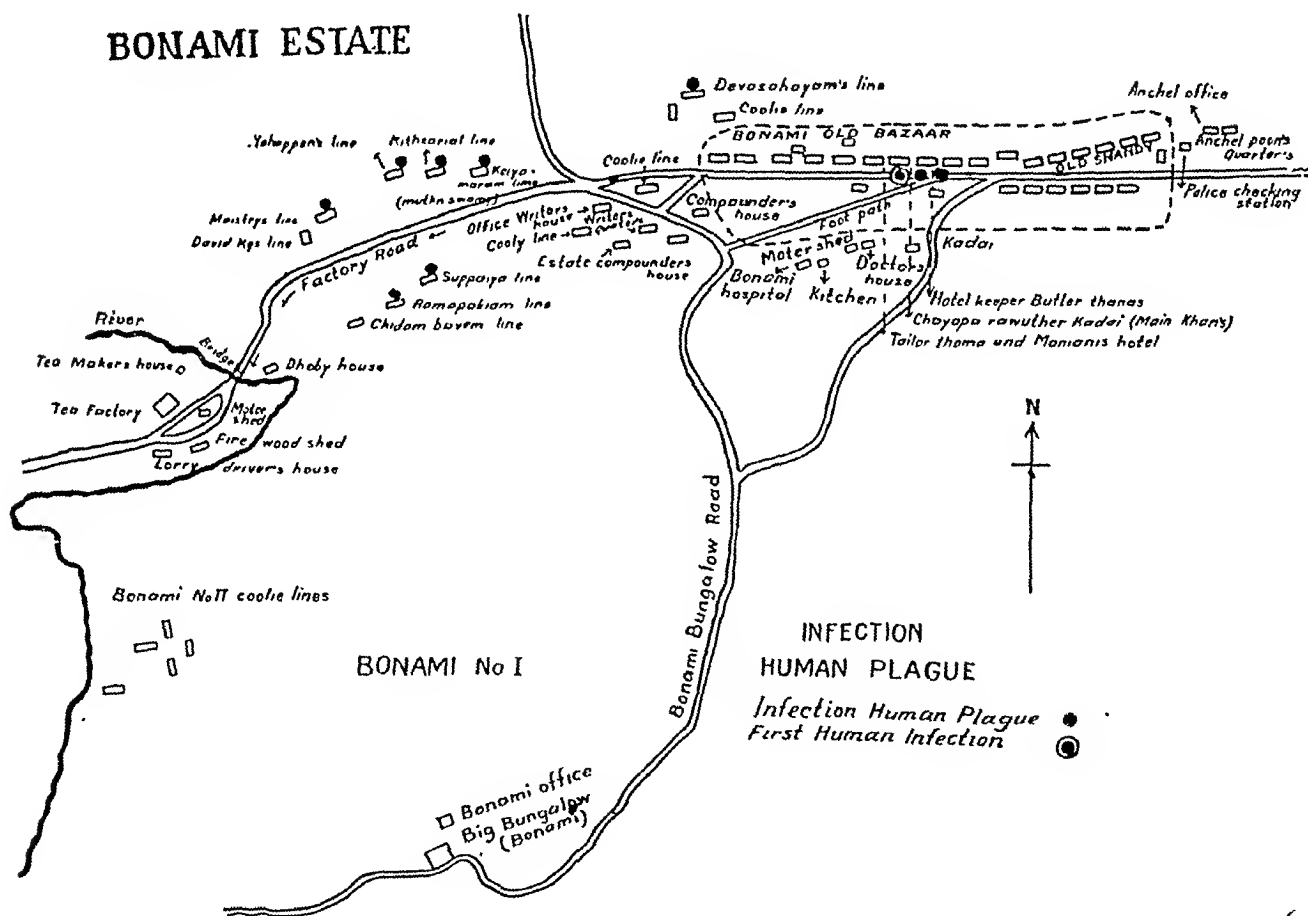

Every estate has one or more rice stores all teeming with rats. In one small rice store, more than two hundred rat holes were discovered. The markets also form important centres of rat population, the chief markets in the taluk being located at Bonami, Pambanar and Vandiperiyar. Rats also abound in the bushes along the main road from Peermade to

number of fleas collected as a result of the survey conducted by the entomological staff was 6,226. The results of identification of these fleas are given in the following table.

TABLE IV
Percentage and classification of fleas in Peermade

Fleas genera	Percentage
<i>X. cheopis</i>	50.2
<i>X. astia</i>	27.2
<i>X. brasiliensis</i>	0.9
<i>Stivalius</i>	9.3
<i>Ctenocephalus</i>	1.4
<i>Echidnophaga</i>	8.9

<i>Ceratophyllus</i>	0.1
<i>Pulex</i>	2.1

MAP I

Cumbum valley; particularly around the usual halting places of the bullock carts where a lot of grain escapes from the bags. These halting places are usually in the vicinity of a group of houses and these become potential centres of plague infection.

A rat-flea survey of Peermade was carried out by Iyengar (1934), Entomologist of the Public Health Department, from September 1932 to March 1933. Two thousand four hundred and seventy-two rats were caught of which 2,463 were *Rattus rattus*, 5 were bandicoots, 3 *Mus* and 1 *Pachyura*. The total

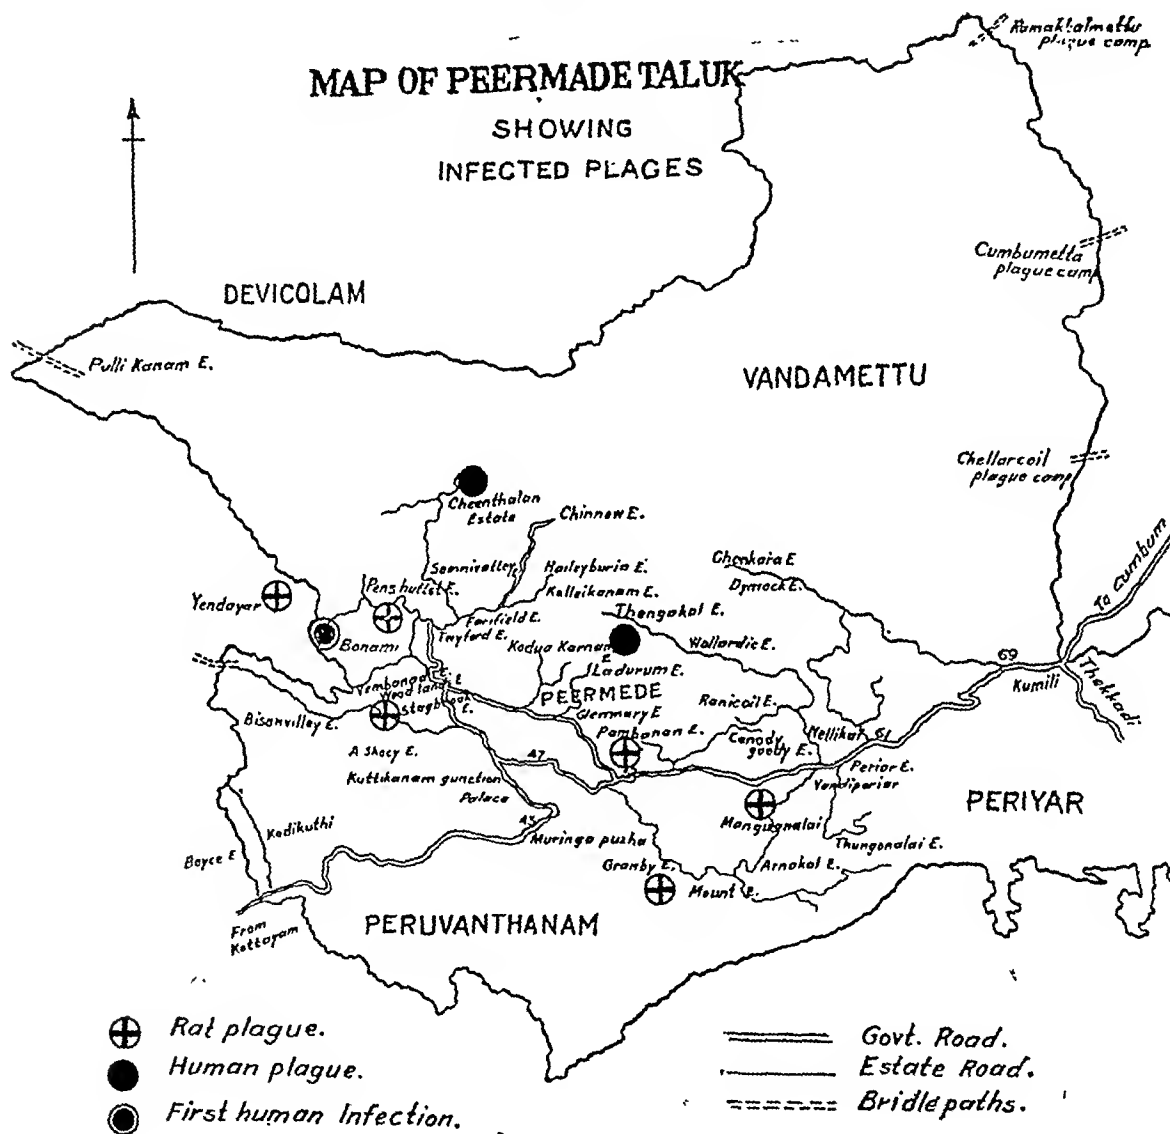

The conclusions of the medical entomologist on the survey are as follows: 'In the high-lying area of Peermade the prevalence of the principal plague transmitting flea *X. cheopis* is extensive. It is as high as 72 per cent in *Rattus rattus* caught in this area. This figure is far higher than is necessary for effective plague transmission as observed in other localities in India. It is difficult to decide whether *X. cheopis* is indigenous or has been introduced from infected areas to the east of the ghats. In the lower region of Peermade *X. cheopis* disappears and *X. astia* is very prevalent'.

Plague outbreak in Bonami in 1932

The plague outbreak in Bonami in March and April 1932 may be considered as the first serious outbreak in the State and the first one that was not immediately brought under satisfactory control. The fact is now recognized that this was due to the late recognition of and notification of the early cases.

The day after the beginning of this illness of Maria her husband Thomas was reported to be sick, but he was brought to my notice only on 2nd April and he also was found to have congestion of lungs. He died on the 3rd April. Another case was one Janamma in the same line who fell ill on the 1st April and was suffering from pneumonia. By the 10th April,

MAP II

With regard to these early cases, the following extract from a report by the medical officer of Bonami estate may be of interest. He states 'that one Maria, wife of tailor Thomas fell ill on 27th March; she had fever for about four days when I was called in. She showed on examination symptoms of pneumonia. She had also mastitis. A boy by name Palaya in the neighbourhood had also an attack of fever on 25th March. He had fever, diarrhoea and rash on the chest and was considered to be a case of enteric. He died on the 29th March.

she developed a swelling below the ear and died of high fever on 14th April. Two more deaths in the same line caused panic and the occupants were advised to shift to the neighbouring lines. The death of one Idichandy, a tailor living in the same line, of plague, at Mavelikkara on the 10th April, revealed for the first time the infection of plague in this locality'.

The first recognized case of plague referred to above was the tailor Idichandy who was working for many years as a tailor in Bonami

consulted me. Forty-two days had passed since the complaint started, even then the consistence of the penis was harder than that of cartilage. There was no trouble with regard to micturition, but he complained of local pain. The dorsal vein of the penis was prominent. I was at first tempted to make multiple incisions as recommended by Romanis and Mitchiner, but later thought of trying the effect of leeches once again. Six leeches of moderate size were distributed one on either side of the body of the penis near the glans, two on the dorsum and the remaining two at the root of the penis. The effect was quite marked, as the leeches sucked in blood the penis became gradually smaller and softer. There was slight oozing for a day, but the bite marks healed up afterwards. So far, there has been no recurrence of the trouble.

Interesting points about the case.

1. Absence of any abnormality even after x-ray examination.
2. No history of sexual excesses or unnatural offences.
3. Persistence of the condition for a period of six weeks without relief.
4. Maximum doses of potassium bromide had no effect on the condition.

Thus two important causes of priapism, viz, sexual excesses and malpractices and the presence of spinal tumours appear to be eliminated in this case. The condition was evidently due to local congestion and two leeches were not enough to relieve it.

Civil Surgeon, Buldana

CASES are on record where it is alleged that persons who have been taken as dead have recovered when about to be buried; also bodies of others which have been exhumed a few days after burial have been found to be in a state of contortion, clearly testifying to a struggle for breath or life. We also hear of persons being in a state of trance, in which breathing or heart beats are scarcely or not perceptible.

The usual signs of death are: stoppage of breathing, cessation of heart beat, lowering of the body temperature, loss of the corneal and pupillary sensibility, and so on.

I recently saw an Indian who could expand his chest thirteen inches, and had perfect control over his heart and blood vessels. He could completely stop his radial, carotid or temporal pulses either singly or simultaneously on both sides for several seconds at a time; he could also stop his heart beats for several seconds and I could not discover with the aid of a phonendoscope even the suspicion of a heart sound, thus showing perfect control over his circulatory system.

There is on record the case of Colonel Townshend who used to say that he could die and come to life again, as he wished. He used to lie flat on his back and his radial pulse

gradually sank till it was imperceptible, his heart became still and his breath used to stop until it did not dim the shining mirror held to his mouth. After a period of several minutes he used to breathe gently and slowly restore himself to animation again.

In the East one comes across Sadhus living chiefly in the jungles and in the mountains, who practise 'Yoga' and who appear to have perfect control over the various systems.

A CASE OF ECLAMPSIA

TREATED WITH 'CHLORAL HYDRAS'

By L. R. LAKHKAR

CAPTAIN, A.I.R.O.

Chief Medical Officer, Kawardha, Kawardha State
(E. S. A.)

On the morning of 3rd April, 1935, I was called in to see a case of delayed labour accompanied by fits. The patient was a young girl, 18 years old and of a good constitution.

Previous history.—Patient's mother died of a similar trouble during delivery. The patient had one abortion two years back.

Present history.—The patient noticed swelling of both feet and legs 15 days previously. On the afternoon of the 2nd April she had pain in the abdomen. It was intermittent and thought to be labour pain. The pain continued for some hours and then disappeared. At 1 p.m. in the night she suddenly vomited and rolled her eyes upwards, her whole body became rigid and began to shake. This continued for 15 minutes. She had three similar attacks before morning. On examination at 7 a.m. on the morning of the 3rd her temperature was 97.8°F.; pulse rate 82 per minute. There was no pain in the abdomen, but the child was alive as foetal heart sounds could be heard. Her legs and feet were swollen and the swelling pitted on pressure. She was made to pass some urine, which on examination was found to be loaded with albumin. A diagnosis of eclampsia was made and treatment started.

Treatment.—An injection of 1/3 gr. morphia was given and 500 c.cm. of blood removed from the right arm by venesection. One hour later, 40 grs. of chloral hydras were given by mouth dissolved in 100 c.cm. of water. The patient had three fits after this. Another injection was given 3 hours after followed by chloral hydras. Chloral hydras was repeated six, twelve and eighteen hours after the first injection. The patient passed no urine during the whole day consequently it was removed by catheter at 8 p.m. The whole genitalia had swollen enormously. At 9 p.m. pains again started and at midnight the patient was delivered of a male child which lived only ten minutes. Surgical asepsis was rigidly observed during the delivery. The patient had no fits after the second dose of chloral. She was given a diuretic mixture next day and castor oil in the night. On the morning of the 5th she had three motions. During the treatment the patient was kept on plenty of milk and water. The urine was free of albumin on the morning of the 4th. The patient subsequently made an uneventful recovery.

CORRIGENDUM

IN Lieutenant-Colonel A. N. Palit's paper on 'Splenectomy for Tropical Splenomegaly' which appeared in our May issue, on p. 244, first column, thirteenth line from the top, the words 'this was one of the patients that died subsequently' should read 'it was one of these patients that died subsequently'.

Indian Medical Gazette

JULY

THE STERILITY OF VACCINES

INDIA is a country in which treatment of many diseases by injection therapy is extremely popular both among the medical profession and their patients, and of all forms of injection that of vaccines is probably the commonest, therefore care in their preparation is of the utmost importance.

Large quantities of vaccines are made by Government Laboratories in India specially equipped for the purpose where due care and attention are paid that the vaccines issued are sterile and safe. These vaccines are generally prophylactic and are used for the prevention of such diseases as cholera, plague and enteric fever, but also large numbers of vaccines, particularly the autogenous variety, are made for treatment purposes. It is in the preparation of autogenous vaccines that careful consideration is required in the selection of the micro-organism to be employed and in the preparation of the vaccine so that the issued article will be non-toxic, perfectly sterile and beneficial to the patient.

One of the most important points regarding the preparation of vaccines is to ensure, as far as is humanly possible, their absolute sterility, because serious and possibly even fatal results may follow their use if living organisms, either those from which the vaccine is made or contaminating bacteria, are injected. In India under present legislation there is no law compelling any tests to be carried out to ensure sterility before a vaccine is allowed to be issued for use or sale, so that all we have to depend on in this respect is the efficiency and conscientiousness of the person preparing the vaccine. As far as we know even in well-equipped public laboratories all that is done is a simple inoculation of a drop of undiluted vaccine on a culture medium and if no growth occurs it is passed as sterile. The cities of India contain private laboratories, many of them small and run by a practitioner as an adjunct to his practice. He may have only one imperfectly trained assistant so that in his case proper sterilization of vaccines will be doubly difficult. We do not mean to infer that such a practitioner is deliberately careless but anyone who knows the amount of sterilization of glassware that has to be carried out during the preparation and bottling of a vaccine will understand how difficult it will be to do this properly in a small laboratory with a limited staff.

The importance of this aspect of vaccine therapy has been recognized in Great Britain

for some years because the Therapeutic Substances Act of 1925 laid down certain 'standard sterility tests' which must be applied to all vaccines before they can be sold. It is considered worth while quoting these rules to indicate how stringent must be the testing of a vaccine before it can be considered safe to use.

The regulations under the Therapeutic Substances Act of 1925 applicable to the 'manufacture for sale' of various therapeutic substances including vaccines (see Second Schedule, Therapeutic Substances Regulations, 1927) lay down standard sterility tests which should be followed.

'The tests shall be made on fluid media, the quantity of medium contained in each tube or other vessel used in the test being such as to ensure that any phenolic antiseptic present in the sample is diluted to less than 0.01 per cent.

In the case of a test for aerobic organisms the medium shall consist either of a meat extract with the addition of 1 per cent of peptone, or of such an equivalent as can be prepared by the tryptic digestion of muscle. After the final sterilization the hydrogen-ion concentration of the medium shall be between the limits represented by $\text{pH} = 7.2$ and $\text{pH} = 7.8$.

In the case of a test for anaerobic organisms the medium shall consist of a nutrient broth similar to that used in testing for aerobic organisms, with the addition of heat-coagulated muscle of an amount sufficient to occupy a depth of not less than 1 centimetre at the bottom of the tube. After the final sterilization the hydrogen-ion concentration of the medium shall be between the limits represented by $\text{pH} = 7.2$ and $\text{pH} = 7.8$.

Before the test inoculation the medium shall be heated to 100°C . for a period sufficient to free it completely from dissolved oxygen, and then cooled to 37°C . or lower.

The inoculated tubes shall be incubated at 37°C . for seven days.

The reason for inoculation of the vaccine into a liquid medium so as to reduce the concentration of carbolic to less than 0.01 per cent is to ensure there are no organisms present whose growth is inhibited in the usual 0.5 per cent carbolic that vaccines contain, but which will grow when the carbolic is diluted, as it will be in the body fluids after injection.

It will perhaps be considered that these rules are too stringent and that vaccines simply tested by a single inoculation on to a solid medium are to all intents and purposes safe. In the vast majority of cases they are, but there is always the possibility of organisms being present whose presence only the above precautions will reveal, so it is worth while carrying out these tests to escape a few avoidable errors in the treatment of our patients.

How far such tests are applied in this country at present is known only to the makers of vaccines, but we venture to express the opinion that there are few who could say they carry out all the above tests for sterility, nor can they reasonably be expected to do so in the present state of the law. We have put forward the above facts in the hope that a beginning may be made in the improvement of vaccine preparation in India, and although we do not hope for such stringent regulations as we have quoted being enforced from the beginning, nor do we

consider the sudden introduction of such a complicated set of rules would work successfully where no rules at present exist, but we suggest

that the introduction of some regulations and restrictions regarding the testing of vaccines might be considered by the authorities.

Special Articles

A SMALL X-RAY BUILDING FOR A MOFUSSIL HOSPITAL

By J. C. DRUMMOND, M.Ch., F.R.C.S. (Edin.)
CAPTAIN, I.M.S.

As many mofussil towns are now being electrified and their hospitals are considering the installation of x-rays, this description of the new x-ray department at the Imambarah Hospital, Chinsurah, may be of some assistance to those contemplating a similar project. The writer has profited from errors made in two previous installations of a similar character and offers this as a suitable design for the needs of an average Sadar Hospital using a six kilowatt self-rectifying plant.

Economy in cost and space has been carefully considered—few hospitals are in a position to ignore these items—the design being cut down to the lowest figure and size compatible with efficiency. An effort has been made to avoid the faults so commonly seen in x-ray buildings in this country such as defects in light-proofing, ventilation, developing arrangements and accommodation for apparatus.

The building described consists of a main room for the plant, a dark-room and a store. It has been built on a well-raised plinth corresponding in height to that of the adjoining hospital building. The height of plinth required will, of course, vary in different localities, but the necessity of keeping the plant dry during the monsoon must be borne in mind. It was first decided to build the plinth on arches to enable under-floor ventilation to be provided, but this plan was abandoned owing to the probability of mould, stagnation and smells developing in the humid conditions of Bengal. In dryer parts of the country, however, it would probably be satisfactory.

Having decided on a solid plinth, the problem of light-proof ventilation was solved by making oblique shafts through the walls at floor level and fitting them with baffle plates. In the case of the dark-room an additional precaution was taken of fitting a hood over the outside of the ventilating shaft. The result was both efficacious and cheap. In the store room, where light-proofing is unnecessary, additional high-level ventilation of the conventional type was fitted.

The main room has internal dimensions of 17 feet by 16 feet, which gives ample room for both x-ray and diathermy apparatus. There are

four windows with well-fitting shutters, the latter being panelled in place of the usual *jhimils*. The door is flush with the floor so that a trolley may be wheeled in without having to go over a door frame. On the bottom of the door on the inner aspect is a 3-inch projecting ledge to minimize light leakage under the door. The plaster of the walls has a chocolate dye incorporated in it, and is painted over with a dull chocolate paint. The floor is of patent stone, chocolate with a black border. The resultant colour scheme is both attractive by daylight and suitable for screening when the room is darkened.

The dark-room opens from the main room through two doors with a small intervening enclosure. This double door system, apart from offering increased protection against light leakage, makes it possible for a person to enter or leave the dark-room while development is actually in progress. The walls of both the dark-room and the intervening enclosure are of black plaster and the floors of black patent stone. On two sides of the room black ferro-concrete shelves are built in, sloping gently to a sink of similar material in one corner. Over the sink at a suitable height is a ball-valve cistern for water storage.

In places where water pressure at the taps is maintained for twenty-four hours, the cistern may be omitted, but on no account should a cistern be placed outside in the sun, as this would make the water too hot to be used for washing the films.

The dark-room window has wooden panels and is made to open. The joints are protected against light leakage by separate laths on hinges. One panel is of ruby glass with a sliding shutter. This is a provision against possible break-down of the electric safelight during development and it may also be used for viewing films before fixation is complete. It had been intended to put a canvas or *chick* shade outside the dark-room window to keep off the direct rays of the sun, but this was found to be unnecessary. Leakage of light through the drain of the sink and through the floor scuppers is avoided by the use of angled pipes.

The store room is provided with a built-in *almirah*, the bottom shelf of which is lead-lined for storage of undeveloped films. As light-proofing is not required in this room, the walls and floors are of brighter colours and both floor- and ceiling-level ventilation are provided.

The power supply in Chinsurah being A.C., no space for a rotary converter is provided,

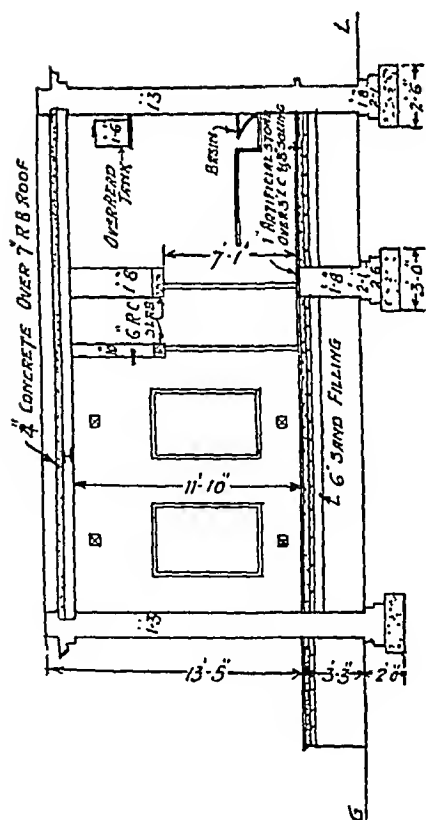

In conclusion the writer wishes to acknowledge his indebtedness to the donor, Babu Rishi

THE ESSENTIALS OF BORE-HOLE LATRINE CONSTRUCTION

By P. A. MAPLESTONE, D.S.O., M.B., CH.B., D.T.M.
(From the Helminthological Research Laboratory
School of Tropical Medicine, Calcutta, Endowment
Fund)

BORE-HOLE latrines appear to be one of the most efficient as well as the cheapest type of latrine for primitive rural communities and the one which it is easiest to induce people to use, especially those to whom sanitary disposal of excreta is a comparatively new idea.

The points detailed below and which are regarded by the writer as the essentials have been largely taken from the writings of C. H. Yeager of the Rockefeller Foundation, which have appeared in the *Malayan Medical Journal* in 1929, and in the *Philippine Journal of Science* in 1931.

The diameter and depth of the hole are two things that must be decided upon before ordering the necessary tools. The "best size" for general purposes is a hole 14 to 16 inches in diameter, so an auger of this size must be obtained. There are many augers on the market but the simplest, most generally efficient and cheapest is the type made by Messrs. Iwan Bros. in the United States of America. This is the only boring tool needed for soil of average consistency such as occurs in most tea districts, but should hard ground or loose sand be encountered modified boring tools will be required. Augers of this type are now obtainable locally (figure 1).

Fig. 1.—Iwan auger (after Yeager).

It is an advantage to make the hole deep enough to enter the sub-soil water level at the dry time of the year, so this should be done if possible. The reason for this is that such a hole, containing water permanently, acts more or less as a septic tank and liquefaction of the stools occurs. The result is that practically all the contents of the latrine will percolate away through the soil, it will not become rapidly filled with solid matter, and will in consequence operate for an almost indefinite period. For the sake of convenience in description we will consider the making of a hole 20 feet in depth.

Shafting of 22 to 23 feet in length will be needed for attachment to the auger to bore a

hole 20 feet deep. For the average soft soil one is likely to encounter in tea gardens galvanized or black piping $1\frac{1}{4}$ to $1\frac{1}{2}$ inches in internal diameter should be strong enough. This shaft can of course be in a single length or it can be jointed so that extra lengths are added as the auger descends. The jointed shaft is easier to transport and handle but it will be more expensive.

Handles for turning the auger are needed, and the simplest form of these is a pair of large pipe-wrenches. If the handles of these wrenches are too short extra leverage may be obtained by slipping a length of pipe over the wrench handle after it is attached to the boring shaft. Such wrenches are often in stock in an engineering store of average equipment, but if they have to be bought specially they will add materially to the total cost of the equipment. A form of turning handle recommended by Yeager is easily and cheaply made locally. This consists of a fourway water-pipe joint of greater diameter than the auger shaft, it is drilled through the centre with a $\frac{5}{8}$ -inch hole and two lengths of pipe of suitable length (about 4 feet) are screwed into two of the opposite openings in the joint. The shaft of the auger is also bored through both sides with a $\frac{5}{8}$ -inch hole about every 2 feet of its length. The handle is slipped over the shaft and can be easily attached to it at any suitable height by a $\frac{5}{8}$ -inch steel pin (figure 2).

Fig. 2.—A turning handle (after Yeager).

The auger has to be lifted and emptied every time it becomes filled with earth so some arrangement for obtaining a vertical lift is a great help as the sides of the hole will not be damaged by the constant raising and lowering of the auger if this is done. A compound pulley with a double block at the top and a single block at the bottom will supply sufficient mechanical advantage to ensure easy and steady

raising of the auger. A tripod of bamboo poles or piping 25 feet in height is erected over the hole with the double pulley block attached to its top; the single block hangs at the lower end and it has a hook beneath it which can be let down the hole to engage the arch of the auger, or in the case of the shaft drilled for the attachment of the turning handle it can be attached to one of the holes in the shaft. A lighter and more easily transported and erected hoisting frame can be made with two poles joined together at one end and erected over the hole in the form of an inverted V. This is held in place by a guy-rope at each side passing from the top of the frame to pegs in the ground.

A platform with a central hole for passage of the auger shaft and consisting of two hinged trap-doors on a frame is not a necessity, but is a great help in holding the auger vertical during the process of boring if placed on the ground over the hole (figure 3). More elaborate types of brace can be bought but they are all fairly expensive and are no more efficient than the above 'home made' one.

Fig 3—Trap-doors on frame to hold shaft vertical during boring (after Yeager).

In some soils a casing may be needed to prevent the soil from caving in and filling the hole. A casing woven from split bamboo has been used with success and will last a long time. Concrete casing for the whole depth of the hole

would be very heavy and expensive, but in places liable to flooding a watertight casing in the upper part of the hole is necessary. This is to prevent faecal matter being washed out of the hole and spread over the surface of the ground, perhaps even being carried into wells by flood water. Reinforced concrete will be found the best for this purpose in all probability, but such things as old oil drums roughly joined end to end will serve if they happen to be available. This casing need not extend very far into the hole but it must project out of it for a sufficient height to be above the level of the probable flood water. If it is necessary to put in this casing it must be packed round with a mound of earth up to its top to carry the squatting plate.

It will probably be found that the squatting plate can be most cheaply made locally and the following figures taken from Prasada (1934) will serve as a guide for the required dimensions. It is 3 feet in length by $2\frac{1}{2}$ feet in breadth, dished $1\frac{1}{2}$ inches from edge to centre and the thickness throughout is 2 inches. The back of the hole is 6 inches from the back edge of the plate and it is 14 inches in length, being 4 inches wide at the front and 5 inches at the back (figure 4).

A squatting plate is essential for several reasons:

1. It prevents the edges of the hole caving in.
2. It prevents the soil surrounding the hole being contaminated with faeces and thus supplying a source for hookworm infection.
3. It can be readily cleaned if it becomes soiled.
4. It prevents small children falling down the hole.

A superstructure of some kind is required over the latrine to make it private, and this can be made of similar material to that employed for the coolies' huts. The advantages of this type of building are that the materials will be obtainable on the spot and the erection can be done by the coolies themselves, each one building his own shelter. Another possibly important point in supplying a building of a type to which the coolie is thoroughly familiar is that he is much more likely to willingly enter such a hut than a strange one of wood, brick or iron. An important point in the erection of the protecting building is to see that the walls are in close contact with the edges of the squatting slab as this will prevent the surrounding soil becoming infected if the latrine becomes dirty, and even if the earth did become infected persons entering the latrine could not come in contact with it from the inside.

If properly constructed and kept clean these latrines are remarkably free from smell so that they can be placed quite close to the houses, and the nearer they are the more likely are they to be used at night or when there is heavy rain.

As far as information is available on the subject it appears that it is safe to allow these latrines to be established to within 100 feet of wells in homogeneous and fine soil without cracks or

PLAN OF SQUATTING PLATE.

Fig. 4.—Plan, front and side elevation of squatting plate (after Prasada).

faults, as all the harmful bacteria will be filtered out of the effluent in less than that distance (Yeager, 1929). It is noted in this connection that Prasada (1934) says 50 feet is considered far enough from wells at Partabgarh.

One of the precautions to ensure the successful working of this type of latrine is to see that each hole is not used by too many individuals, otherwise it will become filled rapidly. Five or six persons can safely use a latrine of the dimensions we have described for a long period, probably several years, if it contains water and

satisfactory liquefaction of the contents takes place.

This is only a brief outline of the main points and precautions to be observed in constructing bore-hole latrines, together with a description of the minimum of equipment needed to do the work satisfactorily. Many alterations and improvements will no doubt be effected to suit special local conditions in certain places by individuals, especially those with ingenuity and engineering knowledge and with a little elasticity in the expenditure allowed, but it is hoped that this note will serve as a basis on which to begin operations.

Medical News

NATIONAL INSTITUTE OF SCIENCES OF INDIA

WE have just received the first issue of the Proceedings of this institution. It gives an account of the formation of the institute at the beginning of this year and the aims and objects of the organization.

In time to come this institution will be most valuable to science in India, for its purpose is to co-ordinate the work of the various scientific bodies throughout the country and to publish in the Proceedings summaries of practically all the scientific matter of importance that is published in India. This will make it an extremely valuable production and one with a world-wide circulation assured. The first number is well produced and closely follows the style of the best English scientific publications, so that as well as being a necessity to all scientific libraries it will be an acquisition on account of its appearance.

TWENTY-SEVENTH ALL-INDIA MEDICAL LICENTIATES' CONFERENCE, INDORE

THE Twenty-Seventh Annual Session of the All-India Medical Licentiates' Conference was held at Indore in a specially arranged pandal in the compound of the King Edward Hall on Wednesday afternoon, Sir James Roberts, Kt., C.I.E., I.M.S. (retired), Member of the Council, Dewas Sr. State, presided. A number of delegates from different parts of India attended the conference.

The chairman, in reviewing its manifold activities in varied branches, alluded to the ceaseless endeavours to remove the stigma of inferiority which had unfortunately attached itself to the class of licentiates. Proceeding, Dr. Khandekar surveyed the rapid advance recorded in raising the standard of preliminary qualifications of medical schools and bringing them into line with the course prescribed for registered medical practitioners.

Adverting to the work that remained to be done in improving the lot of the medical licentiates, the chairman thought it fortunate that the Director-General of Medical Services should continue to lend his support to their cause.

The passage of the Indian Medical Council Bill in the Legislature with such haste was, in the opinion of the speaker, an affront to the association which at the present critical juncture was deprived of the valuable services of such brilliant advocates as the late Dr. K. D. Lohakare who had consistently championed their cause in the Legislature.

Concluding, the speaker stressed the need for a properly equipped school of pharmacy. To assist research work the association had set apart Rs. 10,000 and the speaker pleaded for the recommendations of the Drugs Committee appointed by the Government of India being carried into immediate effect.

This was followed by the annual report read by the secretary which led to lively discussion on several points.

On the evening of the first day an exhibition of scientific and sanitary appliances was opened by the Maharaja of Indore. The second day was devoted to committee work, and on the third day there was a final general meeting when the following resolutions were adopted:

(1) The Government to (a) increase the course of licentiates to 5 years in all medical schools, (b) include them in the Indian Medical Council, (c) give increased representation in the Provincial Medical Councils, (d) enunciate a definite policy regarding honorary appointments in hospitals; (2) the Indian Medical Association to work for the statutory recognition of the licentiates and to bring about uniformity of medical qualifications in India; (3) the universities to allow the licentiates to appear for the M.B., B.S. examination without the restrictions laid as in the Madras University, and (4) the insurance companies to remove the distinction that they make between the licentiates and the graduates regarding the payment of fees for medical examination.

THE SEVENTH INTERNATIONAL MEDICAL POST-GRADUATE CONGRESS

THE Tomarkin Foundation is organizing, under the auspices of the University of Brussels, its Seventh International Medical Post-Graduate Congress officially approved by the General Commissariat of the Government for the World Exhibition.

This congress dealing with diagnostic and therapeutic actualities will be held during the World Exhibition from the 12th to 19th September next in the Faculty of Medicine of the University in Brussels and from 20th September to 2nd October at Spa.

For all particulars please apply to the Secretary, Tomarkin Foundation, Faculty of Medicine, 97, Rue Aux Laines, Bruxelles (Belgique).

THESIS PRIZES

NOTICE is hereby given that the subject for the Dr. Joseph Benjamin thesis competition prize essay for the year 1935 of the value of Rs. 35 (thirty-five) is 'Prevention and Treatment of Malaria' and that for the Dr. Ramchandrier thesis prize for the same year is 'Prevention and Treatment of Cholera'. The value of this prize is Rs. 25 (twenty-five).

All bona fide members of the association (All-India Medical Licentiates' Association) are entitled to compete.

The thesis papers should not be of more than 1,000 (one thousand) type-written lines or their equivalent.

Intending candidates are requested to send their papers to Dr. Joseph Benjamin, President, Gujrat Branch of the All-India Medical Licentiates' Association, Dalgawada, Ahmedabad, so as to reach him on or before the 30th November, 1935.

Notice is hereby given that the subject for the Dr. Joseph Benjamin thesis competition prize for the year 1934, as published in the *Indian Medical Journal* of July 1934 issue, page 415, of the value of Rs. 35 (thirty-five) on the subject of 'Ante-Natal Diseases,

their Care and Treatment' is extended to 30th September, 1935, and that all bona fide members of the Association (A.I.M.L.A.) are requested to compete for the same.

Intending candidates are requested to send their papers to Dr. Joseph Benjamin, President, Gujrat Branch, Dalgawada, Ahmedabad, so as to reach him on or before the 30th September, 1935.

The thesis paper should not be of more than one-thousand type-written lines or their equivalent.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE

At the next congress it is proposed to hold a round-table discussion on nutrition, and we have been asked by the council to make preparation for it.

Papers are invited upon nutrition from the widest point of view and we should be glad if trained observers, who are working on any aspect of the subject in this country, will kindly contribute to the discussion by reading a paper on their work under any of the sub-headings below.

If suitable support is forthcoming, it may be possible to combine the papers received and the discussions in a volume, which would constitute an up-to-date account of nutrition as concerns the East.

It is hoped that some indication of the support which may be expected may be received during 1935, though it will not be necessary for titles of papers to be sent in until a later date which will be notified in due course. Such co-operation will enable the council to know how much time should be allotted for the discussion.

It has been proposed to divide papers under three headings as follows:—

I. Economics to include such aspects as agriculture in relation to human nutrition, *e.g.*, improvement of yield and quality of food crops; horticulture; fruit-growing; stock raising; dairy problems; institutional feeding; food surveys; storage; cooking, etc., etc.

II. Chemical and physiological to include food analyses in the widest sense; vitamin, mineral, fat, protein studies, etc.; metabolism, basal metabolism, energy requirements, specific dynamic action.

III. Clinical studies of disease in relation to food and diet, the feeding of infants during the first year with special reference to development (height and weight); children's diseases in relation to food; nutritional oedema, atypical beriberi; the course of infectious diseases under the influence of food; liver cirrhosis; anemias; skin diseases in relation to food and vitamins; ulcers of the leg; leprosy in relation to food; constitutional diseases, diabetes, obesity, gallstones, gastric ulcer, etc.; clinical value of certain foods, etc.

It should be understood that the above provisional programme is intended to be as wide as possible, and that additional suggestions from those able to make them will be welcomed. It is hoped that the subject of nutrition will receive emphasis from the general and normal point of view as well as from the point of view of disease.

All correspondence should be addressed to: The Director of Public Health, Parapattan 10, Batavia-c., Java, Netherlands, India.

ALL-INDIA OPHTHALMOLOGICAL SOCIETY

FOURTH CONFERENCE

THE above society held its fourth conference at Madras on the 22nd, 23rd and 24th April, 1935. The president elect was Lieutenant-Colonel R. E. Wright, I.M.S. On the first day, Dr. E. V. Srinivasan, on behalf of the reception committee, welcomed the members; the secretary, Dr. G. Zachariah, next introduced Sir Mahomed Usman, who opened the session with a short address which dealt with the history of the Government Ophthalmic Hospital, Madras, and its influence on the spread of ophthalmology in India,

particularly in the direction of post-graduate teaching of recent years. Colonel Wright then delivered the presidential address. In the afternoon a number of papers were read on 'Nutritional disorders of the eye'. The discussion, centred chiefly around keratomalacia or xerophthalmia (these terms being used by speakers as equivalent to the congeries of pathological changes resulting from a polydeficiency in which avitaminosis 'A' appears to play a predominant part). This common condition, familiar to workers in the East for many years, plays a prominent rôle as a cause of preventable blindness. Contrary to views expressed by recent workers in England and elsewhere, skin rashes were not considered more frequent in keratomalacia than in the general hospital population, with the exception of lichen pilaris. The same applies to pyogenic infections in general. The view was expressed that many laboratory workers were unfamiliar with the well developed human disorder as it occurs in bulk; hence certain divergencies of opinion in recent literature.

On the second day, the sessions were held in the Elliot School theatre of the Government Ophthalmic Hospital. An interesting programme of twelve short papers was given by members of the hospital staff on:—

Sympathetic ophthalmia.
Occlusion of the central artery.
White rings of the cornea.
Corneal opacities due to sugar of lead.
Corneal ulcer due to *Glenospora graphii*.
Simple xerosis conjunctivæ.
Tuberculosis conjunctivæ.
Leptothricosis conjunctivæ.
von Hippel's disease.
Birth injury of the cornea.
Clinical aspects of glaucoma.
Modern methods of anæsthesia in ophthalmic practice.
Rare complications of cataract extraction.

The paper on sympathetic ophthalmia read by Dr. K. Koman Nayar showed that the Government Ophthalmic Hospital experience was that this condition was less frequent in Indians than in Europeans. Discussion showed that this was not the universal opinion, Dr. B. K. Narayana Rao (Mysore) was in opposition to the view. Members were enabled to examine the extensive collections of intracranial lesion radiographs, water-colour pictures and stereo-photographs of external diseases of the eye, and the various other exhibits of the museum. A number of clinical cases were demonstrated including a group of 20 patients showing the various manifestations of keratomalacia, patients with acne rosacea, von Hippel's disease, Groenouw's keratitis, xeroderma pigmentosa, thrombosis of the central vein, and two keratoconus cases, the last three by Dr. Narayana Rao. Other papers read were on the 'Rôle of anæsthesia in ophthalmology' and 'Three cases of Groenouw's disease'. Prevention of blindness was discussed at the end of the afternoon session following an exhibition of coloured posters and lantern slides prepared for the Association for the Prevention of Blindness, Bengal, by Lieutenant-Colonel E. O'G. Kirwan. Red Cross posters designed in New Delhi and local Madras posters were also exhibited.

The final session was held in the library hall of the Madras Medical College. Papers were presented on:—

The importance of the study of field of vision on the prognosis and treatment of epidemic dropsy glaucoma.
Detachment of the retina, 26 cases.
Ocular complications due to focal sepsis.
The effects of subconjunctival injections of guaiacal cacodylate in phlyctenular keratoconjunctivitis.
Asepsis of the conjunctival sac.
Some observations on slit-lamp microscopy.
Treatment of immature senile cataract.
Cataract extraction in Aligarh.
Blue sclerotics with congenital syphilis.
Buphthalmos and blue sclerotics.
Diphtheria of the conjunctiva.
Unilateral trachoma.

A short history of incidence of glaucoma in Bengal. Ophthalmoplegic migraine involving the sixth nerve.

The subject of greatest interest was primary non-congestive glaucoma, the Calcutta members bringing forward experience in connection with the recent outbreaks of epidemic dropsy. The fact that in the excessively high tensions of epidemic dropsy glaucoma, field changes and disc changes might be absent for months elicited interesting discussion. Decompression by sclerocorneal trephining was still employed extensively in Calcutta, hundreds of operations having been done in the last few months.

In connection with the prevention of blindness, it was considered by the committee that the responsibility of the governing authorities was insufficiently realized and that certain recommendations should be put before the various authorities in British India and the Indian States. These will appear in due course.

About sixty members attended.

At about the same time that we received the account of this meeting we also received volume III of the Proceedings of this society. This is a volume of about 200 pages nearly all of which is devoted to the papers communicated at the meeting held in Calcutta in 1933. Apart from the opening and presidential addresses these papers numbered 34 and are a valuable collection of observations covering a wide field in the science of ophthalmology. The book is clearly printed and contains a number of well-executed coloured plates illustrating certain of the papers. The society is to be congratulated on this production, and we look forward to the issue of volume IV the contents of which are indicated in the above notice of the Madras meeting.

THE DACCA MEDICAL SCHOOL DIAMOND JUBILEE CELEBRATION

THE Diamond Jubilee celebration of the Dacca Medical School on completion of 60 years and the re-union of past and present students will take place in the Dacca Medical School on or about the first week of July 1935. Past students of this school are requested to join the function and contribute their quota.

ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH, CALCUTTA

THE attention of our readers is drawn to two advertisements in this issue regarding the courses of instructions for the D.P.H. and D.P.H. & Hy. examinations which will commence from the 15th October, 1935, in collaboration with the School of Tropical Medicine, Calcutta, and also the next course for the Diploma in Maternity and Child Welfare commencing from the 15th October next.

INDIAN MEDICAL BIRTHDAY HONOURS, 1935

THE following are the names of medical men and others, associated with medical institutions, in the Indian Honours List of date 3rd June, 1935. We offer them our congratulations:

C.I.E.

Lieutenant-Colonel B. Hogham, Indian Medical Service, Chemical Analyser, Bombay Government.

Lieutenant-Colonel R. Knowles, Indian Medical Service, Professor of Protozoology, Calcutta School of Tropical Medicine.

C.B.E.

Miss M. V. Webb, Chief Medical Officer, Women's Medical Service, and Secretary of Funds under the Presidency of Her Excellency the Countess of Willingdon.

O.B.E.

Mr. H. S. Hensman, Superintendent, Government Mental Hospital, and Lecturer in Mental Diseases, Medical College, Madras.

M.B.E.

Dr. Daw Saw Sa, Private Medical Practitioner, Burma.

Miss W. Thompson, Lady Doctor, St. Luke's Hospital, Chabua, Assam.

Mr. Ethirajulu Nayudu, Assistant Director of Public Health, Madras.

Mr. L. J. A. Rogers, Assistant to the Surgeon to H. E. the Viceroy.

I.S.O.

Mr. W. A. D'Castro, Personal Assistant to the Inspector-General of Civil Hospitals, Rangoon.

Mr. Manwa Ram, Superintendent, Medical Branch Headquarters, Kohat District.

Mr. Muhammed Abdur Rahim, Upper Division Hospital Writer, Hyderabad, Deccan.

*Kaisar-i-Hind Medal**First Class*

Miss E. G. Stuart, Church of England Zenana Mission Society Hospital, Quetta.

*Kaisar-i-Hind Medal**Second Class*

Miss B. Lee, In charge of the Leper Asylum and Orphanage, Uska Bazar, Basti, U. P.

Miss V. Laupers Lauders, Matron, General Hospital, Mandalay.

Miss C. Norris, Mure Hospital, Nagpur.

Miss E. Scott, Senior Nurse, Northcote Police Hospital, Bombay.

Mr. A. B. Cooke, Medical Officer, Salvation Army Hospital, Anand.

Mr. R. V. Shiveshwarkar, Assistant Director of Public Health, Ahmedabad.

*Kaisar-i-Hind Medal**Third Class*

Miss A. Jankinath, Assistant Superintendent, A. P. Memorial Hospital, Fatelgarh.

Mrs. R. Rangacharya Puranik, Lady Superintendent, Dharwar Vanita Seva Samaj, Bombay.

Mr. B. J. Ajwani, Public Health Officer, Sukkur Municipality.

Mr. K. N. Lahari, Medical Practitioner, Gorakhpur.

Diwan Bahadur

Rao Bahadur C. Natesa Mudaliyar, M.L.C., Private Medical Practitioner, Madras.

Rai Bahadur

Mr. Janki Prasad Gupta, Medical Officer, Sadar Hospital, Kheri-Lakhimpur, United Provinces.

Dr. Narbada Prasad Shrivastava, Superintendent of Jails and Civil Surgeon, Khandwa.

Mr. Jatindra Mohan Sikdar, Civil Surgeon, Nowgong, Assam.

Rao Bahadur

Dr. Rajayya Robert Williams, Civil Surgeon (retired), Madras.

Mr. Vinayak Balvant Gokhale, Civil Surgeon, Belgaum, Bombay Presidency.

Vaidyaratna

Dr. Melappakkam Duraiswami Ayyangar, Ayurvedic Doctor, Madras.

Rai Sahib

Babu Jaishi Ram Mehta, Medical Officer of Health, Chandausi, Moradabad District.

Lala Ganga Bishen, Civil Surgeon, Punjab Civil Medical Service, Ludhiana.

Babu Sailendra Chandra Sen, Assistant Surgeon, Gaya Pilgrim Hospital.

Mr. Emmanuel Bunyan, Private Medical Practitioner and Honorary Magistrate, Mhow, Central India.

Mr. Munindra Nath Ghose, Government Chemical Examiner, Calcutta Custom House, Bengal.

Current Topics

Anæmia in Pregnancy

By DANIEL T. DAVIES, M.D., B.S.C., F.R.C.P.

(From the *Practitioner*, Vol. CXXXIV, March 1935, p. 290)

ALTHOUGH pregnancy is a physiological and natural state it occasionally results in derangements of the maternal metabolism so as to produce or activate pathological conditions. It is not uncommon for a latent disorder to become active during this period. A woman who during normal times is able to maintain a normal blood count may during this period of increased demand become progressively and severely anæmic. The offspring depends solely on its mother for a proper and sufficient supply of blood-building substances, which must be adequate to maintain the growing infant over the milk-feeding period. Bunge showed that the liver of a newly-born animal contains weight for weight six times as much iron as the liver of an adult animal and that this iron content of the liver progressively decreases during the milk-feeding period, until the animal is able to ingest iron-containing foods, when it again increases. This increased iron content of the newly-born animal can only be derived from maternal sources and this transfer must on occasion so deplete the maternal reserves as to produce a failure of hæmoglobin manufacture. However anæmic the mother it is usual for the child to be born with a full complement of hæmoglobin, although recent work by Strauss shows that infants of women suffering from anæmia often

develop a severe anæmia during the first year of their lives. It is probable that the supply to the foetus has been deficient *in utero*.

The anæmias occurring during pregnancy can be roughly divided into two groups—the hypochromic which is relatively common and the macrocytic which, in this country, is rare. This latter form, however, is commoner in tropical countries, especially in certain parts of India, where the extremely restricted diet is probably responsible in large measure.

Hypochromic anæmia in pregnancy

A mild degree of this hypochromic anæmia is common in women drawn from industrial areas. Whereas idiopathic hypochromic anæmia is almost a curiosity in the male, any outpatient department furnishes a large collection of this type of anæmia in women. An interesting study bearing on this problem was made recently by Davidson and his colleagues at Aberdeen; they found that the daily intake of iron in the poorer classes was much below what has been regarded as necessary. Many of these families existed on an average intake of not more than 6 mg. of iron per day. This impoverished iron intake, however, was not accompanied by any anæmia unless there were some extra demands. In children up to 14 years of age and in males, in spite of a poor intake of iron, anæmia was conspicuously absent; on the other hand adult females on a similar diet showed a high proportion of anæmia. Anæmia was present in nearly 50 per cent of over

400 adult females. As Davidson points out, the iron requirement for a woman is obviously tidal and it corresponds with the normal functions of womanhood; at this period the iron intake should be optimal and not minimal. It is certainly uncommon to meet this anæmia in women who lead lives of luxury.

Provided the stores are well stocked the healthy woman passes through pregnancy without any fall in her blood count. Some attention has been drawn to the increased blood volume which is present during pregnancy and the slight reduction in red cell and hæmoglobin values which might be seen in consequence of this hydræmia during the first six months of pregnancy. Shelly and I recently followed through 45 women during their pregnancies; the average fall in hæmoglobin was only 8 per cent and the average fall in red cells 280,000 per c.mm. Any count which is below 75 per cent hæmoglobin should be regarded as pathological.

The anæmia may show itself during the first pregnancy but it is more common in multiparæ after several pregnancies. It may not be obvious until after confinement and a severe blood loss during labour may be the precipitating factor. Some patients admit that they were pale before the pregnancy but that there has been an intensification of the pallor since they have become pregnant. Usually the symptoms are more prominent during the last three months when the iron is transferred from the maternal stores to the fœtus. Many of the symptoms are often and too readily attributed to the pregnancy. The languor, anorexia, giddiness, headache and dyspnœa are often regarded by the laity as usual and 'natural' symptoms which must be tolerated. Occasionally these symptoms are misinterpreted and regarded as the early symptoms of 'toxæmia'. A rigorous restriction in diet is often advised and this results in deprivation of iron-containing foods at a time when the need is greatest.

In a woman who becomes anæmic for the first time during pregnancy there is little obviously abnormal except the pallor. If, however, she has suffered from anæmia for many years, and perhaps from exacerbations in former pregnancies, the signs of chronic anæmia are usually seen; there is a greenish tint in the sclerotics, the angles of the mouth are fissured and often painful, the tongue is red and devoid of papillæ, the hair is dry and thin, the nails brittle and spoon-shaped and spleen palpable. Some or all of these signs may be present and they indicate an anæmia of long standing and naturally intensified by pregnancy.

Examination of the blood shows a reduction in the hæmoglobin. The hæmoglobin is frequently around 40 to 50 per cent, while the red cells are 4 millions. The colour index is therefore low. The red cells are poorly stained and may show changes in shape and size, i.e., poikilocytosis and microcytosis. The outstanding feature, however, is the low hæmoglobin content, and usually advice is sought before the hæmoglobin falls below 40 per cent.

One of the most important points in examining a woman thought to be a case of this anæmia during pregnancy is a careful inquiry into her diet; the foods which contain iron, such as red meat, spinach and other green vegetables, are often absent from the diet and this is especially true of housewives of working class families who live mainly on bread and other starchy foods. This restriction of iron-containing foods is a logical explanation for the break-down during pregnancy, and it is well to explain to the pregnant female the need of iron-containing foods, as a prophylactic measure. Of 46 patients who did not become anæmic while under observation throughout their pregnancies none gave a history of a poor diet intake; on the other hand of 26 who developed hypochromic anæmia during or after pregnancy 18 took grossly inadequate diets. Castle and Strauss have also emphasized this association of inadequate diets with anæmia during pregnancy.

Another important examination which sheds light on this anæmia is the analysis of the gastric secretion. The normal acidity of the gastric juice facilitates the absorption of iron from the intestine and it is believed that in achlorhydric states much of the iron in the food is lost. Deficient absorption may be therefore superimposed on a state of deficient intake of iron, if there is a coexistent achlorhydria. A woman is most prone to develop anæmia due to iron deficiency when there is achlorhydria and especially is this true when the extra strain of pregnancy calls forth an increased demand from the iron stores. In the 20 females who were anæmic following their last pregnancy two only showed a normal gastric secretion, the other 18 presented achlorhydria or a marked hypochlorhydria. Castle and Strauss found that not only is achlorhydria of extreme importance in the development of this anæmia, but that even in the normal female there is a decided reduction in gastric acidity during pregnancy; this is corrected in the puerperium. Two patients with a good gastric secretion in the puerperium were completely achlorhydric during pregnancy.

That gastric defect may be the only explanation for the anæmia is shown by the following case: a woman, aged 28, developed an anæmia of 60 per cent hæmoglobin in the sixth month of her second pregnancy; she had not had any excessive blood loss in the past, and took a good varied diet, yet she showed an anæmia which responded to iron and which could only be explained by the presence of a permanent achlorhydria.

An exact proof of the importance of achlorhydria in this connection is forthcoming from the experimental work of Ivy and his colleagues. They have shown that the dog on which a gastrectomy has been performed can be maintained without the development of any anæmia for an indefinite period, provided the diet is adequate in iron-containing substances. When, however, the animal is allowed to become pregnant an anæmia of this type invariably occurs. In one dog this occurred in five successive pregnancies.

There is a good deal of evidence that this hypochromic anæmia is not uncommon during pregnancy, and this is in all probability the resultant of a deficient intake of iron-containing foods in women who show achlorhydria or hypochlorhydria. It is also not irrational to believe that much disability and chronic ill-health associated with pregnancy and the puerperium could be avoided by the early recognition of this disorder.

Treatment is highly successful in this form of anæmia; iron in large doses results in a rise in hæmoglobin, the disappearance of the symptoms of languor and lassitude and a feeling of well-being equal to that of any specific therapy. The only tardy response that we encountered was in a woman who gave birth to twins. It is unwise to force the liberal use of iron-containing foods if there is an existing anorexia or any abdominal upset, especially since iron in the shape of its salts will accomplish the necessary improvement in a much shorter time. A daily dose of 90 grains of citrate of iron and ammonia is usually well borne. It is an advantage to prescribe the iron some two hours after food to be followed by a sweet orange drink, although the iron is usually well tolerated. The dose of 90 grains a day should be administered until the hæmoglobin reaches a level of at least 80 per cent, and it is a good plan to continue with one daily dose (gr. 30) until the pregnancy is over. If in the puerperium the gastric analysis be repeated and a normal amount of hydrochloric acid be found, iron medication can be dispensed with; if, however, achlorhydria persists the need for iron will be permanent and it should be given at least periodically until after the menopause.

Macrocytic anæmia in pregnancy

This form of anæmia is certainly far less common than hypochromic anæmia as an event in pregnancy. Its importance, however, is that it may appear very

suddenly and seriously endanger life. It is interesting to recall that one of the first references to an anæmia of pernicious type was that by Channing, an American obstetrician in 1842. This anæmia shows the blood characteristics of Addisonian anæmia and its response to liver therapy is equally certain. There is, however, one important distinguishing feature which was well realized in pre-liver days and, namely, that the patient showing this 'pernicious anæmia' during pregnancy frequently recovered spontaneously, in sharp contrast to the then fatal issue of ordinary pernicious anæmia.

Since Addisonian or pernicious anæmia is now easily corrected with substitution treatment, it is of course possible to meet a patient known to have had pernicious anæmia and now pregnant. The strain of pregnancy might be responsible for a relapse which would call for energetic treatment; case records have established this sequence of events. Pregnancy may also precipitate pernicious anæmia in a female predisposed to its development by reason of a gastric defect. These events are of necessity rare for pernicious anæmia usually occurs in women past the child-bearing period. The macrocytic anæmia induced by pregnancy cannot be regarded as identical with Addisonian or pernicious anæmia. It is true that there is macrocytosis, and that there is great reduction in the red count and a high colour index. The spontaneous remissions, however, place it in a category of its own; another important feature is the inconstancy of any gastric abnormality, for many patients have shown a normal acidity.

The anæmia may be gradual in its onset or it may develop with great rapidity during the last trimester of pregnancy. Associated with the pallor there is often a slightly yellowish tint to the skin and this may be accompanied by subcutaneous œdema if the anæmia is severe. There is also frequently a fever and a tendency to premature labour, as the existence of œdema may suggest a renal lesion and the real cause remain untreated. If, as sometimes happens, the anæmia appears in the puerperium, the accompanying fever may suggest puerperal sepsis and treatment directed to this condition result in neglect of the anæmia. Several writers have described the obstetric shock which accompanies delivery and emphasize the importance of adequate treatment before this takes place. Recurrences in future pregnancies have often been observed and Whitty believes that in some cases a degree of hypoplasia of the marrow is produced, a condition in which the response to treatment becomes particularly resistant.

The exact cause of this anæmia is unknown, the gastric juice is often normal and there is certainly no obvious dietetic factor. Castle and Strauss, who showed that there is such reduction in gastric acidity during pregnancy, suggest that it is due to a temporary arrest of secretion of the intrinsic factor. It may be that many causes operate and that the condition is a non-specific failure of blood formation. In the macrocytic anæmia as seen in India, Wills has shown that in all probability the cause is a lack of the extrinsic factor in the diet.

The treatment of the condition is the same as that of pernicious anæmia, and the earlier the treatment is instituted, the less risk the mother runs. If the anæmia is severe the active principle should be given intramuscularly. In those whose condition is desperate or in whom labour is imminent a blood transfusion is life-saving. Cæsarean section preceded by a blood transfusion is the method of choice when the patient is seen at term to be severely anæmic. Since auto-agglutination is a potential danger much care is necessary in testing the blood prior to transfusion. Provided the gastric secretion is normal treatment can be discontinued after delivery when the blood has returned to normal. If, however, there is achlorhydria it is safe to regard the patient as an example of pernicious anæmia in need of constant supervision and treatment.

Favourite Prescriptions

By CECIL WALL, D.M., F.R.C.P.

(Abstracted from the *Practitioner*, Vol. CXXXIV, February 1935, p. 226)

Aperients.—Probably aperients are the most extensively used medicines in hospital practice. The official Black Draught, which seems to have obtained an impregnable position in the British Pharmacopœia, is too expensive for hospital use; it is represented now by the Haustus aperient:—

R Magnesium sulphate .. grains 150
Emulsion of chloroform .. minims 7½
Infusion of senna .. 1 oz.

Chloroform is introduced partly as a flavouring agent and partly as a preservative. The emulsion of chloroform is made with tincture of quillaia and is less expensive than the solution in spirit.

The cascara mixture is another favourite aperient; its evolution is of some interest. In 1882 it contained 20 minims of the liquid extract with a drachm of the liquid extract of liquorice and chloroform water to the ounce. In 1901 the cascara was increased to 30 minims, the liquorice reduced to 30 minims, and 30 minims of syrup of ginger was added to prevent griping, and the chloroform water was reduced to half an ounce. In 1914 the cascara went up to a drachm, and instead of the ginger, 40 minims of sal volatile were added. Even this was not sufficiently potent and a compound cascara mixture was introduced and remains the popular aperient mixture:—

R Liquid extract of cascara .. minims 60
Liquid extract of senna .. minims 30
Liquid extract of liquorice .. minims 60
Tincture of hyoscyamus .. minims 30
Tincture of nux vomica .. minims 10
Emulsion of chloroform .. minims 10
Compound decoction of aloes to 1 oz.

As a prescription it savours of polypharmacy and can scarcely be called 'elegant', but it is reputed to be efficient with the torpid bowels of habitual constipation. Personally I doubt whether it is any more efficient than the pil. coloc. c hyose. of the B. P. which, if uncoated, maintains perennial popularity with the same class of patient and goes by the name of 'Uncle Henry'.

Astringents.—The hospital pharmacopœia no longer includes an astringent mixture which formerly was so necessary and popular that a large keg was kept on tap in the receiving-room. Motors have ousted horses, flies, contaminated food and summer diarrhœa. The old formula, however, is worth recording:—

R Aromatic sulphuric acid .. minims 15
Spirit of chloroform .. minims 20
Compound tincture of camphor minims 20
Decoction of logwood to the fluid ounce.

Aromatic sulphuric acid was the famous Mynsicht's elixir of vitriol of the seventeenth and eighteenth centuries, and sentimental regret for its disappearance from the B. P. is mingled with the feeling of satisfaction that it is no longer an important preparation.

Anti-dyspeptic formulae.—In the sixteenth and seventeenth centuries, and probably long before, the value of insoluble carbonates and phosphates in the treatment of dyspepsia was well known; chemistry could not then explain either the nature or the action of the drug, but the reputation of powdered unicorn's horn (narwhal's tooth), of calcined snail shells, of crabs' 'eyes' and crabs' 'claws' of the early pharmacopœias was evidently based on the relief of pain after food on their administration. Aqua Tofana, the favourite poison of the Borgias, seems to have been an acid solution of arsenic: if it was put into a cup made of 'unicorn's horn' effervescence occurred and the arsenic was thrown out of solution—small wonder that the

value of the rare narwhal's tooth was great in those days! Modern chemistry has brought to us other and more easily obtained insoluble carbonates, and we still use them to relieve gastric pain, which was then so often attributed to poison in the food. Until 1901 it was customary to prescribe the insoluble carbonates of bismuth and magnesium in combination with an emulsifying agent such as compound tragacanth powder; when this addition was found to be unnecessary the most popular prescription became the pulv. bismuthi co., of which the patient is told to take a teaspoonful stirred up in water. The composition is as follows:—

R/ Oxycarbonate of bismuth	..	10 parts
Heavy magnesium carbonate	..	25 parts
Sodium bicarbonate	..	25 parts

In the pulvis calcii carbonatis co., prepared chalk is substituted for the bicarbonate of soda. The acid and alkaline gentian mixtures are used extensively, but are so well known that comment is needless. The hospital formula for the gentian and rhubarb mixture is designed for economy:—

R/ Gentian	..	grains 5
Rhubarb	..	grains 5
Ginger	..	grain 1
Sodium bicarbonate	..	grains 10
Peppermint water to fl. oz.	..	½
Macerate for 24 hours and strain		

Such a prescription is satisfactory in a hospital where the medicine is compounded in large quantities, but is not suitable for private practice. A better though more expensive formula would be:—

R/ Tincture rhei compound	..	minims 30
Tincture zingiberis fortis	..	minims 5
Liquor ammonium dilutum	..	minims 10
Tincture gentian compound	..	minims 30
Aqua menthœ piperitœ ad	fl. oz.	½

A favourite prescription for the dyspepsia of chronic alcoholism is mist. capsici sedativa:—

R/ Potassium bromide	..	grains 10
Sodium bicarbonate	..	grains 10
Tincture of capsicum	..	minims 5
Strong tincture of ginger	..	minims 5
Infusion of quassia to fl. oz.	..	½

Fever mixture.—Simple diaphoretic mixtures are often of considerable value when the temperature is high. Mixture ammonium acetate compound is an example:—

R/ Spirit of nitrous ether	..	minims 30
Strong solution of ammonium acetate.	..	minims 30
Aromatic spirit of ammonia	..	minims 20
Chloroform water to fl. oz.	..	½

Cough mixtures.—In the dry stage of bronchial catarrh nauseating expectorants act by reflexly exciting the secretion; to secure this end the drug must be given in doses just short of producing the sensation of nausea. The ammonia and ipecac. mixture of the London Hospital contains 20 minims of the tincture of ipecac. with 3 grains of ammonium carbonate in some camphor water, and the dose of ipecac. is not found to be at all excessive. Acting in a somewhat similar manner is the standard cough mixture which is taken mixed with hot water:—

R/ Sodium chloride	..	grains 3
Sodium bicarbonate	..	grains 10
Emulsion of chloroform	..	minims 5
Oil of anise	..	minim 1/25
Water to fl. oz.	..	½

Seeing that aniseed water is no longer included in the B. P., 5 minims of the aqua anethi concentrata may be substituted for the oil of anise in private practice; moreover, it is often desirable to colour the medicine by adding some compound tincture of cardamoms.

In the more chronic forms of bronchitis the alkaline iodide mixture is of great value. Clinical experience supports the pharmacologist's view that large doses of potassium iodide are of less value than the small ones; the formula is:—

R/ Potassium iodide	..	grains 3
Ammonium carbonate	..	grains 3
Potassium bicarbonate	..	grains 10
Camphor water to fl. oz.	..	½

When the coughing reflex is weak it is often useful to add tincture nucis vomica to the mixture. When there is evidence of bronchial spasm, inhibition of the vagus is desirable; in such circumstances stramonium is often combined with potassium iodide. The mixture potassium iodide et stramonium contains the following:—

R/ Potassium iodide	..	grains 3
Tincture of stramonium	..	minims 10
Liquid extract of liquorice	..	minims 20
Chloroform water to fl. oz.	..	½

The dose of stramonium is small because some patients are readily affected by it; generally it is necessary to increase the dose until it causes some dryness of the mouth and then to make a slight reduction.

Sedative cough mixture.—The most commonly employed is Gee's linctus, of which the formula was borrowed from St. Bartholomew's Hospital—equal parts of paregoric, syrup of squill, and syrup of tolu—but a similar preparation is found in the old mixture scillæ compound:—

R/ Vinegar of squill	..	minims 15
Camphorated tincture of opium	..	minims 20
Emulsion of chloroform	..	minims 10
Infusion of gentian to fl. oz.	..	½

Blunderbuss prescriptions.—The old pathology which obtained for so many centuries held that disease was due to excess or defect of one or more of the four humours: blood, phlegm, black bile or yellow bile, and treatment was based on the hypothesis that the disturbance could be corrected by the administration of appropriate drugs—*contraria contrariis curantur*. Uncertainty as to the action of the drugs led to polypharmacy in the hope that if enough were given some would procure the desired result. The modern reversion to humoral pathology under the more attractive and 'scientific' title of endocrine imbalance seems to be associated with a like expectation. This is apparent not only in the proprietary mixtures of the wholesale druggists, but even in the hospital pharmacopœias.

The last edition of the London Hospital Pharmacopœia contains several examples of formulæ which can be justified only by the results of practical experience; at first sight it would seem to be undesirable to combine pharmacological and chemical incompatibles in the same prescription, for instance, in mixture ammonium carbonate compound:—

R/ Ammonium carbonate	..	grains 4
Tincture of squill (B. P. 1914)	..	minims 10.
Camphorated tincture of opium	..	minims 10
Syrup of tolu	..	drachm 1
Camphor water to fl. oz.	..	½

There is a stimulant and a sedative of the respiratory centre and an alkaline carbonate to interact with the benzoic acid of the paregoric. In the mixture oxymelis scillæ the pharmacologist might ask why the potassium iodide is introduced to increase the bronchial secretion and the opium to check expectation; the formula is:—

R/ Oxymel of squill	..	minims 15
Camphorated tincture of opium	..	minims 20
Potassium iodide	..	grains 2
Dextrose	..	grains 30
Chloroform water to fl. oz.	..	½

Practical experience may show that the pharmacologist's inquiry is indiscreet. Another ultra-modern prescription, seemingly designed as a panacea, but unlikely to captivate pharmacists, pharmacologists or the

older generation of physicians is the mixture *ferri alkalina*, of which the formula is:—

R Citrate of iron and ammonium	grains	20
Sodium bicarbonate	.. grains	15
Solution of arsenic	.. minims	3
Aromatic spirits of ammonia	minims	30
Tincture of nux vomica	.. minims	10
Infusion of calumba to fl. oz.	1	

Possibly because of its eponymous title, Broadbent's mixture retains a measure of popularity. The therapeutic intention is not easy to understand, but it demonstrates that a skilled pharmacist may circumvent chemical incompatibility for about 48 hours. It contains:—

R Ammoniated solution of quinine	fl. drachm	1
Strong solution of ammonium acetate.	minims	15
Camphorated tincture of opium	fl. drachm	1/2
Ammonium carbonate	.. grains	2
Tragacanth	.. grain	1/2
Peppermint water to fl. oz.	1	

In the present overcrowded state of the medical curriculum it is scarcely possible for the student to study intensively the subjects of pharmacy and materia medica. The British Pharmacopœia has become a book of standards. The newly-qualified practitioner needs help in the art of prescribing, and his own hospital pharmacopœia should provide that help; it should enable him to employ those medicines of which he has seen the effect when clerking in the wards. The conditions which govern dispensing in a hospital are, however, different from those which obtain in private practice, and consequently while approving the large majority of the formulæ given in our pharmacopœia, I have pointed out some which might lead to disappointment if prescribed outside the walls of the institution. Perhaps when the promised reform of the medical curriculum is effected, greater stress will be laid upon the training in materia medica and pharmacy, and they will be studied at a period more appropriate than at present. Surely the craftsman should know his tools and how to use them with economy and skill.

Anterior Pituitary and Anterior Pituitary-like Substances: Therapeutic Applications

By EMIL NOVAK, M.D.

(From the *Journal of the American Medical Association*, Vol. CIV, 23rd March, 1935, p. 998)

Up to a few years ago, efforts at anterior pituitary therapy were limited to the use of oral or hypodermic preparations, either of the anterior lobe alone or of the whole gland, in conditions of supposed deficiency, such as adiposogenital dystrophy, pituitary obesity or amenorrhœa, dwarfism or infantilism. In this respect the common practice was almost analogous to the early methods of ovarian therapy in conditions of supposed ovarian hypofunction. Just as the clear differentiation of the ovarian hormones has completely changed the complexion of ovarian therapy, so have the recent advances in anterior pituitary hormonology changed the points of view and methods in pituitary organotherapy. The tendency now is to aim at hormone therapy rather than at mere gland treatment.

The important physiologic advances to which reference has been made have been fully reviewed in previous articles of this series. The present paper, like the one on oestrogenic therapy, makes no pretense of being an exhaustive review, being offered rather as a brief summary and appraisal of the present status of the subject, and including only a minimum of references to the extensive and somewhat bewildering literature.

As a basis for the discussion of the therapy of the anterior lobe, the following hormones have been enumerated as having their source in this structure:

1. The growth hormone, commonly accepted as being the product of the eosinophilic cells.

2. The gonadotropic hormone or hormones; generally believed to be formed by the basophilic cells.

3. The lactogenic hormone, shown by Riddle to be the cause of lactation, but only when the mammary gland is previously subjected to the action of the oestrogenic hormones.

4. The thyrotropic hormones on which the activity of the thyroid is dependent.

5. The fat metabolism hormone.

6. The blood sugar raising hormone.

7. The adrenotropic hormone.

Of all these, only the first two would seem, in the present state of knowledge, to merit any discussion from the standpoint of organotherapy. The lactogenic hormone (prolactin) may perhaps prove of clinical value as a galactagogue, but only one brief report, based on a very small series of cases, has so far been made on this subject. Encouraging results are said to have been obtained.

CLINICAL CONDITIONS INVOLVING GROWTH HORMONE

Growth abnormalities.—The best known of these, gigantism and acromegaly, are due to excessive production of the growth hormone, most often by adenomas of the acidophilic cells. Here the problem is not one of organotherapy but of correcting the endocrine excess by means of surgery or irradiation.

As types of deficiency of the growth hormone may be mentioned the growth deficiencies characterizing the various types of pituitary dwarfism and infantilism, especially the so-called Lorain-Levi and Brissaud types. While these are believed most often to be due to adenomas of the chromophobe cells, the obvious growth deficiency would seem to justify the use of preparations containing the growth hormone. Simmonds' disease (cachexia hypophyseopriva), a rare disorder due to destructive disease of the entire anterior lobe, and characterized by emaciation, a prematurely senile appearance, amenorrhœa and other symptoms, has in a few cases been treated by anterior pituitary preparations, either orally or hypodermically, but the results have not been striking.

Preparations available.—No commercial preparation of the growth hormone has as yet been recognized by the Council on Pharmacy and Chemistry of the American Medical Association, which is not surprising in view of the present inability of manufacturers to prepare it in pure forms, and the meagreness and unconvincingness of clinical reports. In this country only three commercial preparations, so far as I know, are available; viz, the 'Antuitrin G' of Parke, Davis & Co., the 'Phyone' of the Wilb Laboratories and Anterior Pituitary Extract Squibb. These extracts all contain other active principles of the anterior pituitary in addition to the growth-promoting factor. The more purified form of the growth hormone with which Evans has achieved such striking results in animals is not yet available commercially, although the manufacturers to whom it has been entrusted have been able to furnish small amounts for a few clinical and experimental studies. Engelbach in 1930 reported satisfactory growth results in a pituitary dwarf of 9 years in whom treatment with the Evans' purified growth hormone was carried out, with daily injections of the substance, for nine and a half years, 2.7 inches (7 cm.) in height being gained during this period. Engelbach and Schaefer have recently reported encouraging results in seven cases of dwarfism. In these the growth hormone preparation (antuitrin G) was combined with thyroid, which Smith has shown to increase the effect on skeletal growth. Both Evans and Reichert emphasize the importance of having such growth hormone extracts free of gonadotropic principles, which might result in excitation of sex maturity, with epiphyseal closure and the cessation of growth.

There are a few clinical reports by Cushing and others of the use of preparations of the growth hormone in cases of pituitary growth deficiency, but, on the whole, the results have not been impressive. The chief hope for the future seems to lie in the preparation

armamentarium. At times the results seem brilliant, in other cases only improvement without disappearance of the pain is reported by the patient, and in still others the results are disappointing. However, in the treatment of a disorder in which there is so much therapeutic floundering as in that of primary dysmenorrhœa, the plan suggested is worthy of trial, especially as it is far more rational than most others which have been suggested. It should again be emphasized, however, that in all cases of this group there should be a comprehensive survey of the constitutional, pelvic, psychic and even sociologic status of the patient.

In 1933 Brosius and Schaefer reported a case of complete aspermia in which the intramuscular injection of antuitrin S (2 c.e. twice a week) was followed by spermatogenesis, so that at the end of nine weeks numerous motile spermatozoa were found in the semen, while the testes showed a definite increase in size. Needless to say, this observation, interesting as it is, needs confirmation through trial in a large number of cases. In two recent cases of sterility in my practice in which the responsible factor was the husband's aspermia, the method suggested here failed to produce spermatogenesis.

In 1931 Bengtson reported striking results in sixteen cases of alopecia treated by anterior pituitary substance. He recommended the hypodermic use of a pituitary gland preparation as preferable to the oral route, although the combination of the two methods gave the most rapid response. While he considered that all these cases belong to the category of glandular alopecias, he suggested that possibly other common types of baldness might also respond to the treatment. In spite of the author's own conservatism in this regard, the paper was taken up rather sensationally by the daily press. There has been no confirmation of his observations, and Lord and others have reported unsuccessful results from the method. There seems to be no reason to expect benefit from it except perhaps in cases of genuine hypopituitarism in which the alopecia is a part of the general picture. Even here the usual limitations and uncertainties of pituitary therapy would prevail.

SUMMARY

The employment of the growth hormone preparations is indicated in the various types of pituitary growth deficiency. The results are usually not striking and will probably not be improved until biochemists isolate the hormone and produce more potent preparations.

The anterior pituitary-like preparations are probably of no value when used alone in the treatment of amenorrhœa, and even when combined with œstrogenic substance the results are very little improved.

The anterior pituitary-like preparations made from pregnancy urine have appeared to give excellent results in many, though not by any means all, cases of functional uterine bleeding, so that, when this disorder is encountered in young women, in whom radiotherapy is undesirable, the method should certainly be tried.

The comparatively small group of cases thus far reported in which undescended testis has been successfully treated by the anterior pituitary-like preparations make this method seem promising and worthy of more extended trial, especially as the surgical treatment of this condition is not as satisfactory as might be wished.

There is no objection to a trial of the anterior pituitary-like preparations in the occasional mysterious and baffling cases of habitual abortion, although the results are not much more clearly defined than is the ætiology of the condition.

These preparations appear rational as adjuvants in the treatment of primary dysmenorrhœa, although correction of constitutional and psychic factors is often much more important, and should never be overlooked.

As to other conditions, such as aspermia and baldness, the clinical data thus far available are much too meagre to draw conclusions as to the results of treatment with the anterior pituitary-like preparations, and

there are physiologic reasons to make one question the value of this plan.

It is possible that the results of organotherapy in various forms of anterior hypopituitarism may be improved with preparations of the gonad-stimulating hormones obtained from the anterior lobe itself.

The Treatment of Whooping-Cough

By W. T. BENSON, M.D., F.R.C.P. (Ed.), D.P.H.

(From the *British Medical Journal*, Vol. I, 30th March, 1935, p. 657)

WHEN an infant or young child who has not previously suffered from whooping-cough develops a persistent, troublesome cough with scanty clinical signs of bronchitis, and if within two or three days the cough, which is worse at night, tends to occur in paroxysms giving rise to suffusion or blueness of the face and occasionally terminates by a vomit, suspect infection with *H. pertussis*. If in such a case there is a history of recent intimate contact with whooping-cough then the clinical diagnosis can be made with some confidence during the catarrhal stage. Failing a history of exposure to infection the diagnosis may be aided by examination of the blood picture or confirmed by the isolation of the Bordet-Gengou bacillus.

The presence of a leucocytosis (commonly 15,000 to 25,000 white cells per c.mm.) with a well-marked relative lymphocytosis (from 50 to 70 per cent of lymphocytes) is highly suggestive of whooping-cough. For bacteriological diagnosis two Petri dishes containing a special culture medium for *H. pertussis* will have to be obtained from a laboratory. Instruct the parent or nurse to expose the surface of this medium five inches in front of the patient's mouth for fifteen seconds during a natural paroxysm of coughing. Expose the second dish in a similar manner. Should the patient's cough be mainly short, sharp, and occasional, then expose each dish on four occasions. Return the dishes to the laboratory as soon as possible. Should examination of the cough plate after seventy-two hours' incubation show colonies of *H. pertussis* then a diagnosis of whooping-cough may be confidently made. The causal organism can apparently be isolated from approximately 75 per cent of cases during the catarrhal stage of the disease. It is to be noted that a negative report does not exclude the possibility of whooping-cough.

It must be remembered that in infants and in adults the typical whoop may not appear throughout the whole course of the illness; bacteriological aid would simplify the diagnosis of such cases.

GENERAL TREATMENT

Most clinicians with an extensive experience of whooping-cough are of the opinion that when the primary essentials of medical care have been arranged for the patient we have practically exhausted our effective therapeutic armament. Vaccines, drugs, and ray therapy may be regarded as adjuvants to be given a trial when special indications arise.

When whooping-cough is suspected the patient should be confined to bed and strictly isolated from other members of the family who have not already suffered from the disease. Isolation should be enforced for a period of five weeks dating from the onset of symptoms. The bedroom, with a sunny exposure for choice, should be kept freely ventilated, but at an equable temperature around 60° to 65°F. If the weather is warm and sunny the bed may be placed at the widely open window during the day; otherwise the patient should be screened from draughts. The bedclothes should be light yet warm, and the child clothed in a flannel nightgown. A flannel binder firmly applied round the abdomen is of supportive value during the strain of coughing. Some trustworthy individual should be constantly in attendance to support and to comfort the child during the paroxysms of coughing and to have a receptacle ready for the vomit.

Providing the attack is afebrile, uncomplicated, and not unduly severe, the child may be allowed out of bed about the third day of the whoop. When the paroxysms exceed thirty in the twenty-four hours, or when there is a previous history of chest trouble, confinement to bed until convalescence is well established is advisable. If the weather is equable and sunny the patient should spend most of his time in the open air—precautions being taken to avoid contact with susceptible children. The clothing should be warm but not excessive, and mild exercise should be encouraged. The bowels should be regulated by occasional doses of syrup of figs or liquorice powder.

IMPORTANCE OF DIET

The dietetic management of a case of whooping-cough is of the utmost importance. In severe attacks, particularly if improperly handled, the persistent vomiting results in a serious degree of malnutrition. The secret of feeding is to give small amounts at frequent intervals. Large meals should be avoided, and food administered preferably about ten minutes after a paroxysm. For babies 'feeding by the clock' may have to be adjusted to the necessities of the case. If vomiting and loss of weight continue then the interval between feeds should be decreased and the bulk of each feed lessened. Various modifications of the diet may be necessary. The milk may be diluted, boiled and citrated, or peptonized; whey and albumen water may have to be temporarily resorted to. In the worst cases mouth feeding may require to be supplemented by rectal or intravenous saline to which 5 to 10 per cent of glucose has been added. Lavage of the stomach twice daily with 0.6 per cent solution of sodium bicarbonate is a useful measure when vomiting is frequent.

no meals must be avoided, but a diet is necessary. Milk, eggs, butter, fish, chicken, meat, and vegetable soups are better than an excess of potato, bread, milk puddings, jams, and similar starchy or saccharine foods. Biscuits, rusks, oatcakes, or other dry crumbly foods should be avoided. Fresh orange juice drinks sweetened with 5 to 10 per cent of glucose may be freely administered. A prolonged convalescence, with if possible a change of air, is advisable.

VACCINE AND SERUM THERAPY

Very conflicting reports have been published regarding the value of vaccine treatment. It is generally agreed that no improvement can be expected to follow vaccine therapy unless the initial injections have been given during the catarrhal stage of the disease. A vaccine containing *H. pertussis* alone, or preferably, a mixed vaccine containing in addition *H. influenzae* and the pneumococcus, may be employed. Six subcutaneous injections rising from 100 million to 1,000 million Bordet-Gengou bacilli should be administered on alternate days. This method of treatment has been given a prolonged trial in the wards of the Edinburgh City Hospital, but the results have proved disappointing.

Human convalescent whooping-cough serum or whole blood injected intramuscularly on one or more successive days in doses of 10 to 20 c.cm. has been reported on favourably by various French physicians. If circumstances permit this specific method of treatment might be tried in severe attacks in infants.

DRUGS

In spite of the numerous drugs that have been recommended for the treatment of whooping-cough the writer after an extensive experience of many preparations—including belladonna, antipyrine, bromoform, benzyl benzoate, ether, adrenaline, and ephedrine—is of the opinion that none can be looked upon as a specific.

In a mild attack there is no need for medication. If desired a simple expectorant mixture may be administered three daily:

R Tinct. camph. co.	mp iv.
Vin. ipecac.	mp iii.
Syrup. scillae	mp x.
Aq.	q.s.

When the paroxysms are frequent and severe, resulting in considerable exhaustion and loss of sleep, a sedative or ing should be prescribed. One or other sedatives may be prescribed four-hourly: syrup of codeine phosphate, 10 minims; Dover's powder, 1/2 grain; chloral hydrate 2 grains, with ing should be prescribed. If necessary the dose may be increased until either improvement ensues or the child becomes drowsy. ing should be prescribed. Doses of 1/6 grain to 1/4 grain occasionally results in a rapid ing should be prescribed. Because of its toxicity this drug should be employed with discretion. Belladonna is probably the most popular drug in the treatment of whooping-cough: in the dosage commonly prescribed it is quite ineffective. In an endeavour to control the paroxysms belladonna must be pushed to the physiological limit. Commence with three drops of the tincture three times daily; then, providing no idiosyncrasy is present, promptly change to four-hourly administration, followed by a daily increase of one drop per dose until dilatation of the pupils, flushing of the cheeks, and dryness of the mouth indicate that the limit of safety has been reached. During convalescence the patient should take cod-liver oil and malt with some preparation of iron; the syrup of the iodide of iron is excellent.

ULTRA-VIOLET RAY AND X-RAY TREATMENT

Whilst of value as a general tonic during convalescence, particularly in the winter months, ultra-violet light therapy has no specific effect on the paroxysmal stage of the disease. In the absence of pulmonary complications a daily general treatment ing should be prescribed. to both back and front may be tried. This a minute daily care.

Although some beneficial results from x-ray treatment in 75 to 80 per cent of cases, due apparently to a reduction in size of the bronchial lymph glands, other investigators have not been so successful.

COMPLICATIONS

The most important complications of whooping-cough are bronchopneumonia, convulsions, and gastro-enteritis. These complications are most apt to occur in young children, in whom they are a frequent cause of death. Bronchopneumonia usually develops at the height of the paroxysmal stage, and seems to predispose to convulsions. Gastro-enteritis is manifested by frequent profuse diarrhoea in the intervals.

seen but are not of serious importance. is not uncommon. Many forms of paralysis and convulsions.

PROPHYLACTIC MEASURES

Whooping-cough is most highly infectious during the early stages of the disease. It is therefore essential to prevent young children, in particular, from being needlessly exposed to infection with *H. pertussis*. Practically all the deaths from whooping-cough occur during the first three years of life.

Prophylactic vaccination is of value not so much in preventing the development of the disease as in modifying the severity of the subsequent attack. Subcutaneous injections of 8,000 million Bordet-Gengou

alternate days to contacts who have not previously suffered from whooping-cough. The injection of serum or of whole blood of a whooping-cough convalescent or of those who have had whooping-cough at some time in their life has been reported as resulting in complete or partial protection in a large proportion of cases.

For children under 3 years of age 5 c.cm. of serum or 20 c.cm. of whole blood should be injected intramuscularly.

In spite of the multiplicity of remedies recommended in the treatment of whooping-cough an effective therapeutic agent has yet to be found.

Reviews

GYNÆCOLOGY.—By Brooke M. Anspach, M.D. Fifth Edition. 1934. J. B. Lippincott Company, Philadelphia and London. Pp. xii plus 832, with 679 illustrations of which 10 are in colour. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 31-8

THE fifth edition of Anspach's *Gynæcology* is a worthy successor of the previous issues. The first edition appeared only twelve years ago; this is a testimony of the popularity of the work. The chapters on physiology, disturbance of function and treatment by radiation are largely new. The views therein are reliable and up to date. The chapters on diseases of the external genitalia, endometriosis, ovarian tumours, amenorrhœa, uterine bleeding, sterility and dysmenorrhœa have been re-written and modernized.

We think that a great improvement would be effected in future editions if operative gynæcology were dealt with in a separate part of the volume and in a more detailed manner. The performance of a total hysterectomy by the abdominal route—Wertheim's hysterectomy is not being criticized—is described only in a few lines in the present edition. The operation of implantation of the ureters into the rectum is not described at all in the text but appears in two illustrations. We are compelled to point out that it is not in accordance with modern pathology to carry out the removal of any ovarian tumour by 'evacuation of the contents of the largest cyst by means of a trocar, delivery of the collapsed cyst through the incision and ligation of the pedicle'. We do not concur in the recommendation of Watkin's interposition operation and are in complete agreement with the views of another eminent American gynæcologist—Graves—on its numerous disadvantages.

Apart from operative gynæcology, the work is concise, modern and one of well-balanced views. There are one or two statements, however, which we consider unusual; e.g., that non-operative treatment of retroversion is to be preferred during the child-bearing age; that the introduction of a pessary after pregnancy has started in a retroverted uterus is likely to cause abortion. These, however, are minor details and do not detract from the general excellence of the non-operative part of the volume which we can recommend to all interested in the subject. The printing is very good and the illustrations clear and copious.

S. A. McS.

SYNOPSIS OF OBSTETRICS AND GYNÆCOLOGY.—By A. W. Bourne, M.A., M.B., B.Ch. (Camb.), F.R.C.S. (Eng.). Sixth Edition, fully revised. 1935. John Wright and Sons Limited, Bristol. Pp. vii plus 444. Illustrated with numerous diagrams. Price, 15s.

THE recently published synopsis presents the facts concerning obstetrics and gynæcology in the concentrated space of 450 pages. The first half deals with obstetrics, the second with gynæcology.

Both sections have been completely revised and new additions are the sections on obstetric shock and sex hormones.

The author has based his work on well-known textbooks and has enunciated current views with a clarity that is remarkable in a book of this size. A large number of small-sized diagrams are a valuable addition

to a work that has definite value firstly to students preparing for examinations and secondly to practitioners as a means for ready reference.

The author has always wisely insisted that his book must not be regarded as a textbook and students would do well to follow his instructions.

The type though clear is small, and one looks forward to the time when synopses in general are printed in type that will reduce ocular stress to a minimum.

S. N. H.

HYGIENE FOR NURSES.—By J. Guy, M.D., D.P.H. (Camb.), F.R.F.P. & S. (Glas.), F.R.C.P. (Edin.), and G. J. I. Linklater, O.B.E., M.D., D.P.H., D.T.M. & H., M.R.C.P. (Edin.). Third Edition. 1935. E. and S. Livingstone, Edinburgh. Pp. xi plus 212. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 3-12

It is a testimony alike to the usefulness of the book and to the increasing contacts between curative and preventive nursing that a third edition of *Hygiene for Nurses* by Guy and Linklater has been called for less than two years after the publication of the second edition.

The arrangement of the book into personal, communal and social hygiene on the one hand and environmental hygiene on the other is unchanged and the emphasis remains on the former. One or two useful additions on the hygiene of menstruation and the menopause have been made and the chapter on heating has been largely re-written.

The book offers the nurse an excellent introduction to the wider aspects of her duties. Her immediate responsibility is the restoration of her patient to health but if the restored health is to be maintained a new way of life and improved physical surroundings may be necessary, and in teaching this the nurse's responsibilities are heavy and her opportunities many. She will find much help in *Hygiene for Nurses*. A little more space devoted to mental hygiene would perhaps add to the value of an already useful book. The recommendation given to the second edition may be safely repeated for the third.

J. M. O.

MEDICAL CASE-TAKING AND DIAGNOSIS.—By A. J. Kohliyar, B.A. (Bom.), M.D. (Lond.), M.R.C.P. (Lond.). 1935. The Medical Bulletin, Empire Automobile Building, Queen's Road, Bombay. Pp. 133. Price, Rs. 3

THE contents of this book appeared as a series of articles in *The Medical Bulletin*. They are now published in book form, primarily for teaching students on their first joining the hospital. It includes in small compass the kind of information which may be helpful, as a supplement to larger books. A beginner will find it useful in helping him to follow his tutor in clinical medicine. The book consists of fourteen small chapters of which six are devoted to the nervous system (pages 79 to 114). The arrangement is not very satisfactory. On page 3 the author suddenly describes Kernig's sign and Brudzinski's signs while interrogating a patient under 'history and general inspection'. The 'lymphatic system' and 'joints' have been included in the chapter (XIII) on 'urinary system'. Chapter VI

deals with the 'acute abdomen' which really falls within the province of a surgeon. Short theoretical discourses, viz, on aetiology of cardiovascular disease, uræmia, etc., are not appropriate to a booklet of this type, while detailed practical notes on cardiac-efficiency tests, kidney function tests, character of sputum, etc., would have made it more useful.

R. N. C.

INSOMNIA AND OTHER DISTURBANCES OF SLEEP.

—By E. Miller, M.A. (Cantab.), M.R.C.S., L.R.C.P., D.P.M. (Cantab.). 1935. John Bale, Sons and Danielsson, Limited, London. Pp. 53. Illustrated. Price, 2s. 6d.

THIS small book of the 'pocket monograph' series contains a mass of information on the subject of sleeplessness and allied subjects. At the same time the author has not the power of clear expression, and he also does not confine himself strictly to his subject so that there is much extraneous matter included. Psycho-analysis and psycho-pathology take a large place in the book, but without more explanation than there is room for in a book of this size a great deal of this information will not be of much value to any but the skilled psychiatrist. It is hardly a book for the student, and although there is much to be learnt from it the extraction of useful information is not as simple as one usually expects from a miniature volume of this type.

'BODY MECHANICS' IN THE STUDY AND TREATMENT OF DISEASE.

—By Joel E. Goldthwait, M.D., LL.D., Lloyd T. Brown, M.D., Loring T. Swalm, M.D., and John G. Kuhus, M.D. 1934. J. B. Lippincott Company, Philadelphia and London. Pp. xiv plus 281, with 99 illustrations. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 13-8

THIS subject, body mechanics in relation to disease, has at last come into its own, and the medical student of to-day receives in many medical schools, teaching in this important branch of medical science.

The work of the senior author of this book has already received the recognition it deserves. It has been well reviewed in Ogilvie's *Recent Advances in Surgery*, and 'Goldthwait's types' are well known to those surgeons who are interested in the mechanics of the body.

In this book, *Body Mechanics*, there are many excellent charts showing good and faulty postures. These charts are elaborated by diagrams, actual photographs, and skiagrams showing the resultant body sag, and damage done to joints and viscera by poor body position.

The authors show how a large proportion of eye strain can be caused by the forward thrust of the head and neck, which is the result of an exaggeration of the normal curves of the spine due to faulty stance.

They show also how the low position of the diaphragm (again the result of bad body mechanics), by creating a drag on the thoracic viscera, and pressure on the abdominal viscera, can be a large contributory factor in the production of pathological conditions in the chest and abdomen.

The book is good all through, but especially those chapters which deal with backache, arthritis of the spine and joints of the limbs.

Whether however, there will be general agreement that peritoneal bands and kinks, or such conditions as appendicitis and carcinoma of the uterus can be, as suggested by the authors, due to bad body mechanics, is a matter for conjecture.

The treatment advocated consists of graduated exercises designed to overcome faulty posture, and it is claimed that once this has been accomplished, the patient, even if not perfectly cured, will be greatly benefited. The treatment however is very prolonged, for it is suggested that it should hardly ever be less than of one year's duration and in the more chronic cases it may last as long as five years.

The physical culture methods of the drill sergeant of older days have been replaced by new and better ones, and this little book is concerned with these later methods. Medical men and teachers of modern physical exercises, especially those who have the care and instruction of the youth of the present day, would do well to read this book carefully, for prevention is better than cure.

H. E. M.

X-RAY INTERPRETATION.—By H. C. H. Bull, M.A., M.B., M.R.C.P. 1935. Oxford University Press, London. Pp. xxxiv plus 382, with 280 illustrations. Price, 21s.

THE author provides no prefacial apologism for the writing of another book on so familiar a subject. Such apologies containing, as they usually do, references to the 'demand' of an imaginary public are distressingly common and yet they must fail to convince all but a very small minority of readers. The book itself should provide its own justification, as in this case it does—most definitely. Another distinctly unusual feature is the complete absence of all plates or illustrations, other than line drawings.

This has its disadvantages, as the reader who sets forth into the world to read skiagrams with only the knowledge and visual pictures that he has acquired from this book will find himself entirely lost: however, to use a medical book to replace practical experience is to abuse it. On the other hand the presentation of a line drawing ensures that the reader will know what he is expected to see in a skiagram and, if at first he finds considerable disparity between the line drawing, the skiagram, or the fluorescent screen, as his experience advances this disparity will be lessened.

The book is written for the clinician, and as the title indicates it is mainly concerned with interpretation of the picture presented on the fluorescent screen and of the skiagrams, yet there is a certain amount of the technique of radiography introduced, but only in so far as it concerns the patient, that is to say there is no reference to the x-ray plant, tubes, length of exposures, etc., but there are full details regarding the preparation of the patient, the giving of the opaque meals, the posture of the patient and the angle with reference to the screen, etc.

It is difficult to pick out any chapters for special mention, but those on the visualization of the intestinal canal are particularly good; in these a great deal of attention has been given to the subject of normal variations and these associations with persons of different habits.

We can find little to criticize in the book itself and in the excellent way the subject has been presented, but we have one criticism with regard to grammar—the use of 'due to' as if it were an adverb and not a participle, e.g., in the last line of p. 173. This is so common a mistake that in a few years it will have to be accepted as a 'common usage', but we look to publishers like the Oxford University Press to save us from a too rapid change in our language.

It is in every way an excellent book that we can thoroughly recommend to practitioners and students.

INTERNATIONAL CLINICS. VOLUME IV. FORTY-FOURTH SERIES, 1934.—Edited by L. Hamman, M.D. J. B. Lippincott Company, Philadelphia and London. Pp. viii plus 326. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited. Price, Rs. 37-8 per set of four volumes

As is usual, this quarterly publication provides a number of interesting papers on a variety of medical subjects. The paper on vitamin B and vitamin-B deficiencies provides an excellent summary of the present-day knowledge regarding beri-beri, pellagra and the less important B-avitaminoses. The case for and against the B-vitaminosis being the sole cause of beri-beri is well presented and the author obviously veers

towards the middle course, taking the view that deficiencies of vitamin B play an important part in bringing about the syndrome, but that probably there are other factors concerned. One is a little surprised to find no reference whatsoever to epidemic dropsy. It is of course geographically a very localized condition, and its aetiology is uncertain, but a discussion on this condition so closely associated to 'wet' beri-beri would have been very appropriate; perhaps the writer felt that he had insufficient data and in this the Indian workers are somewhat to blame, as, though there has been much discussion on this disease, little epidemiological or even clinical data have been published.

In the paper on the treatment of allergic asthma by desensitization, the writer draws attention to the many factors that influence prognosis in this condition. Perhaps the most important is the inheritance factor; if the patient has a definite family history of hypersensitiveness, the prospects of complete cure are much reduced. Whilst admitting the necessity for treating concomitant infections of the upper and lower respiratory tracts, he points out that these local conditions are often secondary to, and not the predisposing causes of, asthma.

Finally, he points out that by desensitizing the patient you are not getting at the root cause; his cells are still hypersensitive, although they may be desensitized to one irritant, or even a group of irritants; furthermore desensitization is never complete.

There are a number of other articles of considerable interest, including a well-illustrated one on cancer of the cervix uteri, one on the modern concept of sterility, and a good review on progress in dermatology.

L. E. N.

ILLUSTRATIVE ELECTROCARDIOGRAPHY.—By Joseph H. Balnton, A.B., M.D., and J. Burstein, A.B., M.D. 1935. D. Appleton-Century Company, London. Pp. xvi plus 258. Price, 21s.

A NUMBER of very useful books on electrocardiography have been published during the last few years, and even in this company the book under review holds its own. With the exception of a few explanatory pages in general principles, the book consists of 100 plates, each showing from one to half a dozen electrocardiograms with explanatory captions.

The student is taken step by step through the fundamentals of the subject—e.g., the first plate and its corresponding captions explain the method of measuring time and voltage, the 2nd, 3rd and 4th introduce the reader to the waves P, QRS and T, one by one, the 5th and 6th show methods of standardization, the 7th axis deviation, the 8th and 9th variations due to body posture, and the 10th to 14th normal variations—before he is allowed to study the effect of disease on the electrocardiogram. The next 56 plates illustrate clear-cut pathological conditions; these have been grouped into 8 chapters. There is a chapter on multiple abnormalities and one on miscellaneous conditions—such as dextrocardial and congenital heart defects, and a final—very useful chapter on artefacts on the electrocardiogram.

The arrangement of the book is entirely satisfactory as in very few instances is it necessary to turn over a page to consult an illustration referred to in the text and, as the illustrations are all produced upright, the irritation of having continually to turn the book through an angle of 90 degrees is obviated. The oblong shape of the book makes it unsuitable for the average bookshelf—but one cannot have it both ways.

We can recommend this book, alike to the student who is entirely unfamiliar with the subject and has to learn the interpretations of electrocardiograms *de novo*, to the practitioner who has forgotten much that he was taught about the subject as a student, and to the consultant as a book of reference.

PRACTICAL TALKS ON HEART DISEASE.—By G. L. Carlisle, M.D. 1934. Baillière, Tindall and Cox, London. Pp. x plus 153

THIS is a well written book on heart disease as it is encountered in general practice. It is far more suitable for the general practitioner than for the student in the sense that it is not a complete treatise on the subject and that much is left out. For example, the subject of prognosis is really scarcely considered. Dr. Carlisle talks of patients 'living for some years'; obviously in some instances he means that with luck the patient may survive three or four years, whereas in others he means that the patient's expectation of life is only slightly reduced—two very different things. On the other hand every third-year medical student will gain much from reading the first few chapters on methods of examination in heart cases.

The author's principle is that fingers and eyes were made before x-rays and electrocardiographs, and that they should be used exhaustively before any instruments are brought into action; he considers that even the stethoscope is relied upon too much. This attitude is a very suitable corrective to the modern tendency to rely too much on complicated instruments. Particularly so as the advice comes from a university in America where this tendency is even more pronounced than in Europe.

However, some cardiologists will think the writer has gone too far, especially in his belittlement of the stethoscope. Another way in which he seems to have laid himself open to criticism is in his attitude towards exercises during the examination of a patient; he seems to think that they are a waste of time.

The author's style is good but occasionally he has failed to resist the introduction of a trite Americanism. On the whole we consider it a very useful book, and one that every general practitioner will be the wiser for reading.

THE ESSENTIALS OF MATERIA MEDICA, PHARMACOLOGY AND THERAPEUTICS.—By R. H. Micks, M.D. (Dub.), F.R.C.P.I. 1935. J. and A. Churchill Limited, London. Pp. xii plus 395. Price, 12s. 6d.

THIS book is written by a professor of pharmacology who in the preface says he has no personal experience of experimental pharmacology. This lack of experience, however, does not appear obvious in the book for the author has produced an eminently practical little volume. It appears to be arranged on the basis of a course of lectures and this method will be found very useful for purposes of reference as can be seen from the titles of a few of the chapters, taken at random. I. Opium and morphine. General principles; XI. Drugs concerned in the treatment of anæmia. Iron. Liver. Desiccated stomach; XXV. Anthelmintics; and XXIX. Urinary antiseptics.

The author says he has limited the scope of the book to such drugs as are administered internally and are of real value in therapeutics. We presume he does not mean by this that the pharmacopœia should be limited to his selection, but that he has made a careful selection of the drugs that will supply the need of the average practitioner, and in this we agree he has been remarkably successful though we noted one or two omissions with which we are not in agreement (tetrachlorethylene for hookworm infection, for instance).

There is a summary at the end of each chapter which gives the reader an opportunity of rapidly finding out the main points discussed in it. As the author recommends the summary to be read first one cannot see why it was not put at the beginning of the chapter, perhaps the fact that the book was written in Dublin explains this.

In the reviewer's opinion it is a book that can be recommended especially to students for they will find in it all that they need to equip them for the art of prescribing, not the least useful chapter being the last, which is devoted to prescription-writing and which contains a delightfully frank but very true paragraph on

placebos and the necessity for prescribing them in general practice.

THE JOURNAL OF TECHNICAL METHODS AND BULLETIN OF THE INTERNATIONAL ASSOCIATION OF MEDICAL MUSEUMS, No. XIV.—Edited by M. E. Abbott, M.D. 1935. Published annually from The Medical Museum, McGill University, Montreal. Pp. 134. Illustrated. Price, \$2.00 per copy

To those who work in connection with medical museums, and who are interested in the collection and preservation of pathological specimens, this journal with all the useful information contained therein is invaluable. It comprises all the most recent and tested methods and museum techniques and contains also valuable articles from skilled technicians and specialists on the subject.

The present volume begins with an obituary note and a frontispiece portrait of Dr. William Henry Welch, the renowned pathologist and a remarkable personality in John Hopkins Hospital.

The editorials cover a wide range of subjects. Of the original publications, the article written by W. Boyd on the idea of a clinical pathological museum is of particular interest to those who are teachers of pathology and medicine. The possibilities of such a museum is unlimited and it may be made the centre of teaching in a medical school. The underlying idea is to illustrate in graphic form, for the students, the principle of the correlation of the gross and microscopic lesions with the clinical findings and x-ray picture. The original history and autopsy notes are also placed at the top of a specimen to complete the references. The author has illustrated his method with photographs of the museum of Winnipeg to make the display more attractive and at the same time instructive. Portraits of masters of pathology, and coloured drawings relating to particular diseases, etc., are placed in appropriate places throughout the museum. The seats have been made more comfortable so that the students are attracted to spend longer hours in the museum for solid study, without being fatigued. The next article deals with the method of teaching morbid anatomy to students at autopsy. The most useful part, as pointed out by the authors, in autopsy instruction is a review of the various reports and findings on the case, which is held the next week. An illustrative article on the Osler pathological collection in the medical historical museum of McGill University is written by M. E. Abbott, curator of the museum. No one can read the work and writings of Sir William Osler without a feeling of great respect and admiration for that great physician, his clear descriptive style, accurate observations and his insight into the ætiology of disease. The rich and monumental collections of autopsy materials display his genius.

The next section deals with various improved museum techniques. The method of mounting flat specimens in frames in the tropics, described in detail by Tull, will be found very useful specially for those who have scarcity of materials. In another article the advantages of lighting display for museum specimens have been shown. Preparation of bone specimens by Wagoner and Nuckols is an exhaustive monograph on the subject. Improved technical methods have been adopted for ensuring the durability of the specimens and also for teaching students. Artistic methods for labelling museum specimens have also been described.

The next section deals with photographic methods and gives details of technique for infra-red photography.

The microscopical technique for the identification of amœbæ in tissues is an improvement on previous methods. Then there are several case reports of cardiac and vascular anomalies. In addition to all these valuable articles, a few pages have been devoted to abstracts of current medical literature on museum administration and museum technique. One who desires to have

up-to-date information on museum work cannot do without this journal.

M. N. D.

ONCHOCERCIASIS WITH SPECIAL REFERENCE TO THE CENTRAL AMERICAN FORM OF THE DISEASE. PARTS I, II, III AND IV.—By R. P. Strong, Ph.B., M.D., S.D., J. H. Sandground, D.Sc., J. C. Bequaert, Ph.D., and M. M. Ochoa, M.D. 1934. Harvard University Press, Cambridge. Pp. xlv plus 234. Illustrated

THIS is a book in four separate parts each contributed by a different author.

Part I by Richard P. Strong is an exhaustive account of onchocerciasis disease in Guatemala from every point of view. This is the only part of the world where this disease is of real importance to human beings so the account is naturally almost wholly devoted to this country. Adequate discussion is given, however, of the possibility of the presence of a similar disease in Africa and elsewhere, caused by other species of onchocerca.

Part II by Jack H. Sandground can be dismissed with the comment that it is an ideal presentation of the revision of a nematode genus and might well serve as a model to all systematic helminthologists.

Part III by Joseph C. Bequaert is a useful summary of our knowledge of the life history and breeding habits of Simuliidæ and gives a general discussion of the worldwide distribution of this family of diptera. It ends with a taxonomic discussion and gives the diagnostic differences of the species important in America as carriers of this infection.

Part IV by Miguel Muñoz Ocha is a short account of the epidemiology of onchocerciasis in Guatemala and serves as a supplement to part I.

The volume is printed on heavy art paper and the illustrations are numerous and beautifully reproduced.

This is no. 6 of 'Contributions from the Department of Tropical Medicine and the Institute for Tropical Biology and Medicine', Harvard University.

We have not seen the other five numbers of this excellent production, but if they are of the same standard as the one under review they would be well worth acquiring. The book is only bound in paper, which is a pity as it is worthy of a much more impressive cover, possibly this has been done with the idea of reducing its cost. Unfortunately the price is not stated.

P. A. M.

INDIVIDUAL HEALTH. A TECHNIQUE FOR THE STUDY OF INDIVIDUAL CONSTITUTION AND ITS APPLICATION TO HEALTH.—By E. Obermer. Volume I. *Biochemical Technique.* By E. Obermer and R. Milton. 1935. Chapman and Hall, Limited, London. Pp. xvi plus 244. Illustrated. Price, 15s.

To be able to prevent disease by the promotion of health Obermer advocates a complete and exhaustive study of each individual with a view to assessing his or her functional efficiency so that the very earliest signs of dysfunction, strain and lowered resistance can be detected and treated before the disease has obtained its hold.

His study includes assessment of hereditary constitutional factors, external environmental factors and reaction of internal environment to present external environmental factors. He has included all these examinations under the term 'Adaptational Survey'.

The present volume written jointly with Milton describes the biochemical part of the technique of the 'Adaptational Survey'. The technique of the biochemical part of the investigation is very comprehensive including (1) the weighing and measuring of food for a twenty-four-hour period, (2) quantitative analysis of all the normal blood constituents, (3) detailed examination of each lot of urine passed over a period of twenty-four hours, (4) faecal analysis and (5) respiratory metabolism, etc.

Part I of this volume deals with the collection of specimens and their preliminary distribution. Part II

gives the details of the analytical technique. In view of the huge number of examinations required the methods described are for the most part microphotometric. Part II will serve as a useful handbook to workers in analytical chemistry who have to deal with a large number of specimens.

D.

PHYSICAL CHEMISTRY FOR STUDENTS OF BIOLOGY AND MEDICINE.—By David I. Hitchcock, Ph.D. Second Edition. 1934. Baillière, Tindall and Cox, London. Pp. xi plus 214, with 28 figures. Price, 12s. 6d.

This handy volume has been written with the object of enabling the students of medicine and biology to gain a working knowledge of the science of physical chemistry in order to appreciate modern biological research. The importance of physical chemistry as a basis for the explanation of the fundamental physiological phenomena is now well recognized and textbooks dealing with different aspects of the applications of physical chemistry in biology and medicine are very welcome. A preliminary discussion of some fundamental principles of physical chemistry has been followed up by some application of the principles, and a series of problems are set forth at the end of each chapter. These problems are very useful for the student in elucidating the principles explained, but they might have been followed by the mathematical solutions especially for the inquiring reader who is not guided by a teacher. In twelve chapters the author discusses a wide variety of subjects such as gas laws, solubility of gases, surface tension, viscosity, vapour pressure of solutions, diffusion, osmotic pressure, electrolytes, mass action, hydrogen ion concentration, colorimetric and electrometric determination of pH absorption, colloids, membrane equilibrium, equilibria in blood, reaction velocity and enzyme action, oxidation reduction potential and transformations of energy. In the second edition, these discussions are followed by a dozen laboratory directions for experiments which the student may carry out with profit. The apparatus suggested are simple in nature so that they may be found in most laboratories. There are some references in each chapter to special monographs and to journal articles and there is a bibliography at the end so that a reader who is specially interested in the subject may conveniently pursue the study further. It is a stimulating handy volume and will repay careful study.

S. G.

PHYSIOLOGY. (CATECHISM SERIES.) Fourth Edition. Part II. 1935. E. and S. Livingstone, Edinburgh. Pp. from 87 to 158. Price, 1s. 6d. Postage 2d.

THE systems taken up in this handy little book have been well written. Though it is a small book it contains useful and accurate information. The reviewer finds it to be a good book for ready reference by students and thinks it will be of great help to them in preparing for their oral examination. This part has been as well written as part I. The paper and printing are good. The publishers are to be congratulated on their achievement.

P. D.

A SHORT PRACTICE OF SURGERY.—By H. Bailey, F.R.C.S. (Eng.), and R. J. McNeill Love, M.S. (Lond.), F.R.C.S. (Eng.). Second Edition. 1935. H. K. Lewis and Company, Limited, London. Pp. viii plus 987, with 731 illustrations of which 84 are coloured. Price, 30s.

THE fact that a second edition of this book has made its appearance in a little over two years since its first publication is a true indication of its merit and appreciation of its authors.

Present-day surgery makes such rapid strides that a book soon becomes out of date, so Mr. Bailey and Mr. Love have completely revised their work in this

volume and have rewritten many of the original chapters.

Following the practice which was adopted in the previous edition, and in other books by these authors, advanced surgery and the more rare conditions are relegated to small type, so that a candidate for a qualifying examination can review in a rapid manner the more essential facts by confining himself to the material included in the larger print.

The book is on the short side, but it contains all the essential points which one would expect a 'Short Practice' to contain.

Whenever necessary, or wherever it is deemed to be a help to the student, the authors have included embryology and pathology. These subjects are well but scantily dealt with which is only natural in a volume of this size.

The book follows the usual scheme in that it begins with bacteriology, wound infection, follows on with gangrene, the granulomata and, finally, with the surgery of the various regions.

There is an interesting chapter on blood physiology and transfusion, and at the end of the book there is an extremely well written and practical chapter on infections of the hand.

The all important subject of appendicitis comes in for a great deal of discussion, and the merits and demerits of the Ockner-Sherren delayed method of treatment of the acute appendix are contrasted with those advocated by the immediate operative school, the authors being careful to maintain an impartial standpoint.

The true position of McBurney's point is described, i.e., between $1\frac{1}{2}$ inches and 2 inches from the anterior spine of the ileum upon a line joining that point to the umbilicus.

'The erroneous usurper which unfortunately has been copied from book to book is the point at the junction of the outer and middle thirds of the same line. This is much too medial'.

The section dealing with fractures bristles with good advice to the student; not the least being 'Always take x-ray photographs, even in cases in which there is but the merest possibility that a bone may be fractured, for it has been said that bones are not filled with red marrow, but with black ingratitude'.

A truism this, for in no other branch of surgery is laxity or alleged laxity in treatment so damaging to the reputation of the practitioner. One of the best chapters in the book is that on diseases of the breast; the description of carcinoma of this organ being very good and accompanied by several splendid coloured plates.

If we may point out a defect in an otherwise excellent description, the barrage method of radium treatment of carcinoma of the breast receives but a bare mention.

The book is beautifully printed on good paper, and contains 731 illustrations, 83 of them being coloured plates.

It is undoubtedly one of the best of the shorter textbooks on surgery.

H. E. M.

THE PRACTICE OF REFRACTION.—By Sir Stewart Duke-Elder, M.A., D.Sc. (St. And.), Ph.D. (Lond.), M.D., Ch.B., F.R.C.S. Second Edition. 1935. J. and A. Churchill, Limited, London. Pp. xv plus 383, with 180 illustrations. Price, 12s. 6d.

THIS is the second edition of this book which first appeared in 1928. The greater part of the text has not been altered but the book has been brought up to date by the addition of chapters which include the new work on the treatment of refractive errors, on the ætiology of myopia, the treatment of muscular imbalance and of squint by orthoptic methods, the refractometer and the use of contact glasses. The book is somewhat smaller than the first edition, this has been accomplished by cutting out some of the matter which seemed to be redundant.

The book is divided into six sections which deal respectively with eye-strain, refraction, accommodation and convergence, muscle balance, clinical methods and finally spectacles.

The whole subject of refraction is dealt with in a simple and essentially practical manner. The author points out that the book is clinical rather than theoretical but at the same time the art of refraction can only be mastered by careful and painstaking practice in a hospital in which large numbers of cases of various kinds are available.

The book on the whole is a most excellent one, well illustrated and written in a clear, simple style. It will be found invaluable to students and medical men interested in the study of ophthalmology.

E. O'G. K.

THE TREATMENT OF RHEUMATISM IN GENERAL PRACTICE.—By W. S. C. Copeman, M.A., M.B., B.Ch. (Cantab.), M.R.C.P. (Lond.). With a foreword by Sir W. Hale-White, K.B.E., M.D., F.R.C.P., Hon. LL.D. Second Edition. 1935. Edward Arnold and Company, London. Pp. viii plus 228. Price, 9s.

THE attitude of the medical profession towards diseases of the rheumatic group has undergone a considerable change during the last two decades. This can be explained partly as a natural evolutionary movement; with the advances in medical science its central objective has been raised to a higher plane—it is now the saving of health rather than the saving of life alone. This has meant that much more attention is being focused on chronic invaliding diseases such as rheumatism. An outward and visible sign of this changed outlook has been the establishment of the Red Cross Clinic for Rheumatism in Peto Place where seventy-eight thousand patients were treated last year.

Dr. Copeman has played an important part in the organization of this clinic. From his book on the treatment of rheumatism much was therefore expected and from the fact that the first edition was sold out in a few months it is obvious that expectations were fully realized; this second edition will, we foretell, prove quite as popular and it is hoped that the 'printing' has been sufficiently large to satisfy the inevitably greater demand.

No serious rearrangement has been made in the present edition, but certain chapters have been rewritten and all have been brought up to date. The treatment by gold salts has been introduced into this edition and there is reference to the revival of the 'bee-sting' treatment which has been rescued from the indigenous system (of Great Britain and probably many other countries) and resuscitated during the last year—much to the joy of the news-hungry lay press.

The pendulum of opinion regarding their aetiology is swinging away from the toxic origin of chronic rheumatic conditions towards the metabolic. Dr. Copeman's opinion is that a septic focus can be found in, say, 15 per cent (our figure) of cases; there is possibly an undiscovered focus in another 10 per cent, but not in the remaining 85 per cent, as some writers of the last decade seem to think. The remaining 75 per cent may be due to some causative factor which is no longer active, or to an inborn or acquired error of metabolism. With this very liberal attitude towards the aetiology of rheumatism it is obvious that he is unlikely to advocate any panacea for its treatment, and, in fact, he does not; nor does he condemn any of the popular methods, but is usually content to sound cautionary notes, though sometimes he says frankly that he has never seen any improvement following certain of them.

He gives the treatment of pain an important place and from this point of view his book will have a special appeal to the practitioner.

Whilst all right-minded medical writers must deplore the venial foibles, as well as the more serious ones, of his fellow practitioners and whilst it is justifiable to

refer to them in lectures by way of warning to students, they should be exhibited in medical writings as little as possible—for many reasons, not the least being that the writer who harps on them is liable to adopt a Pharisaical attitude. In this matter the author is not entirely innocent. One paragraph frankly puzzles the reviewer; it seems to him to be nothing short of a shadow boxing display. 'Pyramidon... may.... be equally correctly described as dimethylamino-antipyrin or even as dimethylamino-phenyl-dimethyl-isopyrazolone. This sort of thing carries a pseudo-scientific cachet which seems to be much exploited nowadays'. Who is it that is censured—the manufacturer, because he calls it pyramidon when it is really dimethylamino-etc., or because he lets us know that what he calls pyramidon is really dimethylamino-etc., or is it the practitioner because he prescribes dimethylamino-etc., or because he prescribes pyramidon and says casually to his patient 'Of course you know this is really-dimethylamino-etc.'? If a drug has a complicated chemical formula, it doesn't really seem to be an occasion for blaming the manufacturer. Admittedly every medical man won't be any wiser when he is told the full chemical name—but some will, and, in view of recent work, e.g., that on the aetiology of granulocytopenia (to which we found no reference in this book), no medical man should prescribe any of these analgesics without knowing more about their composition than the proprietary name tells him.

After this irrelevant digression, the reviewer feels that he cannot do better than summarize his general opinion of the book by saying that it gives an excellent presentation of the recent, more enlightened attitude towards the treatment of this most important of all invaliding diseases and that it is the ideal book for the general practitioner.

L. E. N.

BLOOD GROUPS AND BLOOD TRANSFUSION.—By A. S. Wiener, A.B., M.D. 1935. Baillière, Tindall and Cox, London. Pp. xiv plus 220, with 72 tables and 41 figures. Price, 18s.

THIS medium-sized book fulfils a need.

The facts concerning isohæmagglutination and the allied phenomena are adequately narrated. Their serological basis, as usually conceived of, is lucidly explained. Directions for practical work are full and the illustrations are excellent. The latter include figures, photographs and protocols of actual experiments. The table of racial distribution of the blood groups is comprehensive.

The mathematical propositions and procedures, in dealing with genetics and biometrics, are very simply given and prove the fact that it is possible to state a proposition without indulging in a morbid display of erudition in symbols or distorting letters of the alphabet. It is not necessary for any reader to skip this section of the book, as has been allowed for in the preface.

After an adequate statement of the usual categorical conception of the isoagglutinogens A, A₂ and B and their corresponding isoagglutinins a, a₂ and b the recent conception of an anti O agglutinin and its relation to the agglutinin a₂ has been duly introduced. Actually in the book the agglutinins have been designated α and β instead of a and b.

The agglutinogens M and N have probably been discussed for the first time in a book in English. Directions for their detection are as full as those given for detecting A, A₂ and B.

The medico-legal section is interesting and instructive. The five agglutinogens A, A₂, B, M and N will decide the question of paternity (and maternity) of a child in a much more reliable way than the mere resemblances which in infants and young children are mostly subjective.

The chapter on the technique of the transfusion of blood is well written. All the up-to-date contrivances have been described, including the *athrombit* containers

which retard coagulation for 30-60 minutes. The treatment of the subject of transfusion from a clinical point of view, however, is hardly an advance over what has been given in older books.

The findings from original papers have been collected and arranged in a logical sequence. Only two discrepancies arrest attention: (1) Figure 8 on page 16 shows a rapid increase of the agglutinins up to age 5-10 and then it almost uniformly declines up to 90-100. This occurrence has been described on pages 7 and 8 rather differently, thus: 'Further, the titre of the agglutinin in very young and old individuals is usually lower than that of the middle-aged individuals'. (2) On page 46 the detection of the transfused red blood cells of a different group, in the circulation of the recipient, some time after the transfusion, seems to be a direct evidence of the life of a red blood cell and not indirect.

There appear to be only two printer's errors: (1) On page 86, in an equation, 'a p' is situated higher than it should be. (2) The table 51, which appears to be important from the context, is missing.

Concerning the exposition of Mendel's laws a question may be asked. Having every rational right to represent the dominant green of the pea seeds by G (capital letter), why do authors insist on representing the recessive yellow by g (small letter). What is wrong with G (capital) and y (small)? A similar query is permissible concerning the alpha and the beta designating the isoagglutinins. What is wrong with the small letters a and b when the capital letters A and B designate the isoagglutinogens?

The book should be in the hands of all interested in blood groups.

Abstracts from Reports

ANNUAL REPORT OF THE INSTITUTE FOR MEDICAL RESEARCH, KUALA LUMPUR, FEDERATED MALAY STATES, FOR THE YEAR 1933. BY P. H. MARTIN, ACTING DIRECTOR

MALARIA RESEARCH

The substitution of atabrin for quinine on estates

Work on the treatment of hospital patients with atabrin has been reported in the Annual Report for 1932. That work has been followed by an extensive study of the advisability of substituting atabrin for quinine in the treatment of malaria as it occurs on rubber estates, that is, among ambulatory patients who do not need in-patient hospital treatment.

Three series of experiments have been undertaken by Dr. Green.

In the first series, the efficiency, cost, and convenience of a mass treatment of all persons living in the estate lines with atabrin, followed by selective treatment of individuals who are subsequently found to be infected with malaria, has been compared with an ordinary quinine treatment, as frequently given in such lines. The treatment technique of this series could be undertaken only on an estate provided with a microscope and a dresser who is proficient in the examination of blood films. Dr. Green also discusses several important side-issues, such as the difficulties encountered by an estate dresser in administering quinine in curative doses in lines, also the influence exerted on the experiments quoted, and on the designing of any line of treatment by the constant changes in personnel. The experiments demonstrated the good effect on the spleen and parasite rates of giving curative doses of an anti-malarial drug (atabrin), as opposed to the common practice of giving quinine gr. x daily, for long and indefinite periods. The investigation was unavoidably terminated at the end of six months. The analysis of treatment given shows that the whole atabrin-treated group only required about one-quarter of the number of day treatments required by the quinine-treated control group, while each individual treated with atabrin was also under treatment for little over one-quarter the number of days of each individual treated with quinine. The costs in two instances chanced to coincide.

In the second series of experiments, all individuals, including new-comers, were given a preliminary five-day course of atabrin, and all cases subsequently showing any kind of fever were re-treated with atabrin. The scheme was intended to simulate conditions on an estate which was unprovided with a microscope. In spite of the fact that nearly half of the labourers were attacked with malaria during the seven

months of the experiment, the working efficiency of the group was maintained at a high level. The cost of atabrin per month per unit of population proved to be 75 per cent greater than the corresponding cost in the previous experiment.

In connection with the examination of about 800 persons, to whom the above two series of experiments relate. Dr. Green's records show that 323 cases of fever occurred. In 149, or 46 per cent of the 323 cases of fever (all proven by use of a clinical thermometer), malarial parasites could not be found in the thick films taken prior to treatment and examined by the staff of the malaria research division of this institute. This result is of particular local interest with regard to occurrence of 'fevers of unknown origin', since the method of blood examination by 'thick films' is the most efficient known, and during the experiments there had been no unusual incidence of influenza, measles, dengue, or other known febrile disease.

Since some of the advantages of atabrin noted in estate practice may have been due to comparison with quinine given in ineffective doses, the third series of experiments was planned to contrast atabrin treatment with quinine, given in short courses but in curative doses. Even should the quinine course be less effective as regards preventing relapses, three such curative courses of quinine could be given for the cost of one course of atabrin. Every case of malarial fever is receiving either a six-day course of atabrin or, for the control group, a seven-day course of quinine, in which every effort is being made to ensure that each day twenty grains of quinine are actually taken by patients of the control group. The experiment is still in progress, but figures obtained so far indicate a superiority of short curative doses of quinine over the prolonged courses, with an average dosage of ten grains daily.

In connection with experiments on the cost of different anti-malarial drugs, Dr. Green points out that the eventual expenditure on such drugs will depend on the facilities for malaria transmission on any particular estate, and consequently upon the efficacy of anti-larval measures. Further, if a patient has to receive in-patient hospital treatment, the difference in cost between atabrin and quinine becomes insignificant, since the total cost of either drug forms such a small part of total hospital charges.

Again, with regard to convenience of administration and to procuring an efficient course of anti-malarial treatment for each infected labourer, the fact that the daily curative dose of atabrin can be given at one muster, also the willingness of the labourers to take atabrin without fear of cinchonism, both assume considerable importance.

Tebetren

Dr. Green has treated 100 cases of malaria with tebetren.

His observations tend to confirm the opinion that tebetren is efficient in direct proportion to its hydroquinine content, which is about 80 per cent. No special advantage has been found by which tebetren is likely to overcome the disadvantage of its present high price.

A comparison of the properties of quinine, atebirin, and tebetren has been compiled. This comparison has been based on the initial degree of infection of the patient as shown by the number of malarial parasites per cubic millimetre of blood just prior to treatment. The effect of all these drugs, in respect of the points considered, appears similar, except that atebirin shows a marked superiority in preventing relapses.

'C. 77'

'C. 77' is a new drug, not yet released for general use, evolved by Professor Giemsa in conjunction with the manufacturers. At the request of Professor Giemsa, a small supply of this drug has been tested in the treatment of 21 patients. The drug has been found to be well tolerated, and its clinical action appears similar to, though slightly slower than, that of quinine.

Totaquina

A clinical trial of totaquina was commenced in 1932, and has been continued in 1933.

A series of over 400 cases of malaria has been treated either with totaquina or with quinine as a control. The scheme of treatment with totaquina was evolved locally, but approximates to that which the Malaria Commission of the League of Nations decided to adopt in 1933. Dr. Field's results have therefore been submitted in considerable detail to that Commission.

Totaquina is required to conform to definite standards. There are two different methods of production which may acquire economic importance in the future.

The findings are that totaquina is an effective anti-malarial drug slightly, but not significantly, less efficient in the immediate treatment of acute malaria than quinine, when either drug is given in curative dosage. Since it must conform to a standard in regard to its active principles, it is much to be preferred to the unstandardized and very variable cinchona febrifuge. The price at which it will be available must be a deciding factor in determining the extent of its adoption.

Natural infection

Examination of mosquitoes for natural infection has shown *A. umbrosus* with both mid-gut and salivary gland infections. This has been the first local confirmation of Barber's findings for 15 years.

A number of precipitin tests have been carried out to determine the origin, human or animal, of the blood on which trapped mosquitoes have fed.

Animal malaria

As a probable further complication in assigning significance to the finding of malaria-infected mosquitoes, comes the discovery that two other local mammals, namely, the flying-fox (Malay 'Kluang') and the common red-bellied squirrel (Malay 'Tupai') are infected with parasites of a malarial type.

Nothing has yet been found out as to the transmission of these parasites, but Dr. Green has already shown that monkey malaria may be confused with human malaria when local anopheline mosquitoes are dissected.

Yellow fever

Blood from 50 Malays was sent to New York at the end of 1932 for investigation as to the presence of substances protective against yellow fever. A report has been received from Dr. Sawyer stating that in no instance was any evidence of the presence of a protective substance found, which result supports the view of the Rockefeller International Health Division that yellow fever has not been in the Far East.

Rocky Mountain spotted fever and tropical typhus

In that field of research devoted to the elucidation of the complex and ever-enlarging group of typhus-like fevers throughout the world, attention has recently been focused on the determination of the degree of relationship that exists between the various entities of the group.

By means of 'protection' tests and cross-immunity experiments in laboratory animals, many interesting results have been obtained. In particular, the relationship of the Rocky Mountain spotted fever to other of the typhus-like fevers has received special attention. Thus, the immunological identity of Rocky Mountain spotted fever and the typhus of Sao Paulo has been shown.

Protection tests suggest the lack of any close relationship between Japanese river fever and South African tick-bite fever on the one hand, and Rocky Mountain spotted fever on the other.

The relationship of the *fièvre boutonneuse*, that occurs along the Mediterranean littoral, and Rocky Mountain spotted fever has been investigated by Parker, Badger and others in the United States of America, and by Brumpt in France. The former group of workers regards the two diseases as closely allied; the latter worker, as differing markedly.

Clear distinctions exist between Rocky Mountain spotted fever and the endemic typhus of the United States of America. Laboratory animals immune to the *tsutsugamushi* disease prove to have no immunity against Rocky Mountain spotted fever.

Towards the end of the year 1933, the collaboration of this Institute was invited by Dr. R. R. Parker (in charge of the Rocky Mountain Spotted Fever Laboratory, Hamilton, U. S. A.), with a view to an investigation of the relationship of the two types of tropical typhus that occur in Malaya, with Rocky Mountain spotted fever. The method of exchange of the respective viruses has been as follows: Nymphs and adults of the wood tick, *Dermacentor andersoni*, infected with the virus of spotted fever, have been received from Hamilton and successfully 're-activated'. Experience having shown that tissue virus of the two types of tropical typhus will not survive transportation of eleven days' duration, transportation in an insect vector is necessary; and for this purpose Dr. Parker has kindly forwarded to this laboratory a supply of uninfected *Dermacentor andersoni*. These have been allowed to feed on infected guinea-pigs of the 'Seerangayee' ('K') and 'Manickam' ('W') strains of tropical typhus, then removed, and returned to Dr. Parker for re-activation by feeding on guinea-pigs in his laboratory.

The experiments appear to demonstrate that immunization of rabbits to high titres with cultures of *Proteus OXK* or *OX19* affords no degree of immunity against subsequent infection with rickettsial passage virus derived from laboratory animal strains of the tropical typhus-Japanese river fever group of fevers, which passage virus is known constantly to provoke agglutinins to such cultures in rabbits infected by it; and, conversely, that the presence in rabbits of an immunity to the above rickettsial passage virus, with accompanying presence in the serum of agglutinins to cultures of *Proteus OXK* and *OX19*, in no way modifies the development of agglutinins evoked by subsequent successive inoculations of cultures of these *Proteus* strains.

THE UNION MISSION TUBERCULOSIS SANATORIUM, AROGYAVARAM, NEAR MADANAPALLE, SOUTH INDIA, ANNUAL REPORT, 1933-1934. BY THE ACTING MEDICAL SUPER-INTENDENT

Short history

The Union Mission Tuberculosis Sanatorium is an institution established by the united efforts of several missionary societies working in South India.

The first steps towards it were taken in 1908, when a few medical missionaries talked over the possibility of such an institution. On 24th October, 1912, the representatives of seven missions organized the U. M. T. Sanatorium Committee. This committee took over a small temporary sanatorium, which had been maintained for two years in Madanapalle by the American Arcot Mission. At the same time, an extensive and beautiful site was secured four miles outside Madanapalle, and in 1913 the building of the sanatorium was begun.

On 19th July, 1915, the U. M. T. Sanatorium was officially opened by the Governor of Madras.

As the sanatorium stands to-day its construction and equipment have cost about Rs. 4,00,000. Of this amount the Government of Madras has provided Rs. 1,60,000 as building grants, while the Sanatorium Committee has found the remainder Rs. 2,40,000 from other sources.

During the nineteen years of its existence, 5,649 patients have been admitted.

Situation and climate

Arogyavaram, the name given to the sanatorium, is situated in North Latitude 13° 33' 37", and East Longitude 78° 32' 45" and is about 2,500 feet above sea-level.

The distance from Madanapalle Road Station, on the M. and S. M. Railway, is four miles on the road to Madanapalle.

The climate is dry, as the average rainfall for the whole year is about 28 inches. Fresh winds blow almost all the year round. The hills, which at some distance encircle the place, act as a protection against too heavy monsoon storms. Being situated on land covered with vegetation away from crowded habitations, the sanatorium enjoys an atmosphere free from dust. During the cold season the maximum temperature usually ranges between 70° and 80°F.; and during the hot season, April to May, between 95° and 102°F. The nights are always refreshingly cool. As the climate is more or less equable, all seasons are beneficial for the treatment of tuberculosis.

The sanatorium grounds

The sanatorium owns about 300 acres of land, of which about 200 form the compound proper. There are 126 separate blocks and buildings and 104 thatched buildings including temporary wards, kitchens and servants' houses.

In the compound are flower gardens and also vegetable gardens. A part of the grounds has been converted into a park with seats and shady walks for the women patients, while in the rest of the sanatorium roads, pathways and seats amid beautiful surroundings have been provided for the men patients.

The sanatorium with its extensive grounds, many buildings, roads with electric lights, its water system, church, school, post and telegraph office and a population of about 700, has come to have all the elements of life in a small town, while enjoying all the advantages of the open country.

Maintenance

The sanatorium is a mission institution supported by the annual contributions of the co-operating missions. At present fourteen missionary societies constitute the union. The sanatorium receives an annual grant from the Government of Madras. Beyond the

income from these sources, the sanatorium is financially dependent on the income from paying patients and on private donations.

Object and methods

The object of the sanatorium is to offer to consumptive patients in India such help as medical science is able to give. It is run on the same scientific lines which have proved successful in Western countries, but with such modifications as are required by the special local conditions.

In earlier years sanatoria were primarily intended for the treatment of only early cases of tuberculosis, but modern developments and experience in the treatment of the disease have shown that they are the best places for the treatment of many of the cases of advanced disease as well. This is our experience also.

During the last fourteen years, since 1920, out of 3,163 patients discharged and included in our medical statistics, 572 or 18.1 per cent were in stage I or early cases, 695 or 22.0 per cent in stage II or medium severe cases, while 1,896 or 59.9 per cent were in stage III or advanced cases.

Accommodation

The number of beds available in the sanatorium, which in 1915 when it was opened was 109, is now 230.

There are nine general wards, with a total of 134 beds. Seven wards contain eighteen beds each, five of these wards forming a unit for men, and two a unit for women. To each of these units is attached a smaller ward with four beds, intended for Anglo-Indian men and women respectively.

Two semi-general wards have been constructed containing four beds each, respectively for men and women.

The special wards contain each one or two beds; in the latter case the ward is divided by a partition.

The illustrations in this report show that the above account of its surroundings is in no way exaggerated. Also the photographs of the wards, operating theatre, electrical treatment rooms, etc., show that the equipment is very up to date. This institution appears to be doing valuable work.

WAR OFFICE REPORT ON THE HEALTH OF THE ARMY FOR THE YEAR 1933. PRICE 2s. 6d. POSTAGE EXTRA

In the following abstract we have only noted that portion of the report which deals with the Army in India, and even from this we have been compelled to omit a great deal of interesting matter. Our readers, especially those interested in public health, are referred to the original in which they will find a great deal of very valuable information.

Principal diseases affecting the troops

Cerebro-spinal meningitis.—Hitherto only sporadic cases have occurred among British troops at rare and irregular intervals. Among Indian troops, cases have been more common, particularly in certain recruiting battalions. The disease, as it occurs in India, is of a severe and fulminating type, and death frequently ensues within 48 hours of the onset of the symptoms. The mortality rate is extremely high, averaging 70 per cent over five years.

The disease has of recent months shown a marked increase among the civil population and the situation presents several disquieting features.

Dengue.—As heretofore, the majority of the cases of dengue has occurred in the personnel of garrisons in seaport towns. Owing to the proximity of the barracks to areas occupied by the civil population, the problem of eliminating the vector of the disease is a very difficult one.

Sand-fly fever.—The figures for sand-fly fever have remained at a very constant level for the last three years. The majority of cases continue to occur in Northern India, particularly in certain stations on the North-West Frontier.

The disease has been the subject of special investigation during the year.

The entomological aspect of the problem has been studied in Landi Kotal, where the investigations were directed by a specially-trained worker detailed by the Indian Research Fund Association. The exact local conditions required for sand-fly breeding were defined, and, once this had been done, no difficulty was experienced in locating innumerable breeding places. So widespread are these conditions that the problem of control appears, under Indian conditions, to be practically insoluble. In compact and well-administered areas such as Landi Kotal itself, something might be accomplished; in straggling cantonments such as Peshawar, the problem is a hopeless one. Work is, nevertheless, being carried out to determine the best method of treating breeding areas so that this knowledge may be available should special circumstances arise calling for its application.

The investigation of the etiology of the disease has produced interesting results, and it can confidently be stated that sand-fly fever of the Indian Frontier is not leptospiral in origin.

On the other hand, experiments which are not yet in a final state leave little doubt that a filter-passing virus is responsible, and attempts are being made to obtain this virus in a fixed form, in the hope that this may prove a stepping stone to the production of some form of immunizing agent.

Fevers of the typhus group.—An increase in the number of cases of this condition which have been diagnosed is probably to be attributed to a more widespread knowledge of the subject. Including all ranks British and Indian, and their families, 44 cases, with 1 death, were reported.

While the disease is more common in certain localities than in others, it is nevertheless widespread throughout the country.

No definite progress has been made as regards the detection of the vector of this disease in India, but opinion is gaining weight that the tick is by no means the only arthropod involved.

Diphtheria.—Diphtheria is a disease in which the information given by the laboratory can on occasion be very confusing. In the straightforward case with clinical signs no difficulty exists. Treatment is inaugurated at once on the strength of the clinical data, and the laboratory affords confirmation of the correctness of the procedure. In cases which clinically are suggestive, but doubtful, the result of the examination of a swab is invaluable. But in those cases of sore throat where no suggestion of diphtheria exists, but where a precautionary swab is taken, the outcome is often dire confusion. Experience has shown that innocuous diphtheroids which are morphologically indistinguishable from *Corynebacterium diphtheriae* are of relatively common occurrence. Where such are found in the swab, few clinicians will accept the responsibility of treating the case other than as one of diphtheria until negative information is afforded by biochemical or biological tests. This involves the swabbing and segregation of contacts, and frequently leads to numbers of men being unnecessarily off duty.

To minimize this as much as possible, special investigations have been made into the technique of isolating and testing the virulence of the organism, and a method has been devised which reduces considerably the interval of time necessary to give a definite result.

Dysentery.—The 1933 figures are slightly higher than those of 1932, but the variation is trifling. Nevertheless there has been in the last ten years an upward trend in the admission ratio for these diseases.

A study of the different types of infection in bacillary dysentery throws an interesting light on the epidemiology of the disease. Some 15 to 20 types of dysentery bacilli, of which 10 are of comparatively common occurrence, can now be differentiated. Occasionally there may be a group or series of cases which is caused by the same type of organism and is therefore referable to a common source. More frequently, however, this is not the case, and, if an analysis is made of the types of bacilli in all cases occurring in a regiment in one season, it will be found that great diversity exists and that few, if any, of the cases are etiologically related to one another. In other words, infection is not due to case-to-case spread within the unit so much as to a constant bombardment from the massive and varied reservoir which exists among the civil population.

Enteric fevers.—The variation in the number of cases occurring among British troops in these three years is trifling. In the year under review, as compared with last year, there was a decrease of 8 admissions for typhoid fever, 8 for paratyphoid A and 1 for paratyphoid B, and an increase of 2 for the enteric group, thus giving an overall decrease of 15 cases.

The position as regards diagnosis remains unchanged. Early blood culture is without question the most satisfactory method. Faeces and urine culture lend little assistance, and the agglutination test, while on occasion it may be of positive value, is of no negative significance. For use in this test, concentrated suspensions of organisms are being issued, with satisfactory results. Owing to the certainty with which batches of suspension can be prepared of a uniform standard the 'standard agglutinin unit' is being abandoned, and results will be expressed in terms of the denominator of the dilution in which standard agglutination occurs, an interpolation table being used where necessary.

The proportionate admission ratio, case mortality and death ratio among men over 1 year's service and under 1 year's service are:—

	Over 1 year	Under 1 year
Admission ratio ..	1	4
Death ratio ..	1	2.1
Case mortality ..	1	8.6

There are various causes which may contribute to this state of affairs. Assuming exposure to infection to be more or less universal and inevitable, susceptible individuals, who have little or no resistance even after inoculation, are likely to be picked out early in their Indian service. Naturally developed immunity will be higher the longer the man serves in the country, and in the same way repeated inoculation may have a cumulative action. Also the older soldier becomes more experienced in looking after himself.

Malaria.—In discussing malaria incidence in 1933, comparison will be made with the incidence in 1932 and in 1924. These two years have been chosen because, within recent times, the former was the best, and the latter was the worst, malaria year for British troops in India.

In India, the most important factor is the weather. On meteorological grounds alone it is easy to understand why 1933 was a worse malaria year than 1932; but these grounds do not serve to explain why it was so much better than 1924. Meteorological conditions in 1933 were unusual. In the June to September period the rainfall was much above normal over the whole of India, the north-east and Burma excepted.

Marked local excesses in rainfall are quite common; but it is very uncommon to find such generalized and heavy excess as occurred in 1933.

The dominance of meteorological conditions over malarial incidence is well seen if the malaria figures are studied in conjunction with the rainfall-temperature-humidity reports issued by the India Meteorological Department; but as, to the general reader, the study of masses of figures is a wearisome business, the

table which follows provides merely enough data to illustrate the general effect of weather conditions on the three selected years—1924, 1932 and 1933.

TABLE
Meteorology—mean of all India

	Worst malaria year (1924)	Best malaria year (1932)	Year under discussion (1933)
Period June to September—			
Rainfall: Percentage departure from normal	+8	—3	+14
Temperature (°F.): Departure from normal	+0.4	+0.5	—0.6
Relative humidity at 8 a.m. (per cent): Departure from normal	0	—2	+2
Whole year—			
Malaria incidence per 1,000.	206.8	84.1	103.3

Anti-malaria finance remained unchanged. The decision, made in 1931, to abandon the mosquito-proofing of barracks until the financial situation improves, still holds good. The value of mosquito-proofing is shown at Mian Mir, now known as Lahore Cantonment. In this notorious station the average annual malaria incidence for the five years 1923 to 1927 was 743. Proofing was carried out in 1927 to 1930. The average annual incidence, 1928 to 1933, was 124.4.

In 1933 there were two important factors in favour of a good malaria year.

Firstly, in 1932, malaria incidence for British troops was unusually light and the 'carry over' of infection to the following year was comparatively small. The importance of this as regards the 1933 figures need not be stressed.

Secondly, in 1933, the administration of plasmoquine was standardized and general.

In the report for 1932 it was stated '.... the tentative opinion is now expressed that the more extensive and intelligent use of plasmoquine is mainly responsible for the fact that 1932 was a record year'.

The opinion is held that, had it not been for the standardized, general use of plasmoquine, the 1933 figures would have been a good deal worse than they actually were.

It is now possible to draw certain general conclusions from evidence obtained by trained observers working on a perfectly controlled and disciplined population, viz—

1. It has been shown that, under the strictest conditions, quinine-plasmoquine can effect a remarkable reduction in malaria relapse rates.

2. Under general practice conditions this reduction is not so striking. Thus, in 1933 the relapse rate for quinine-plasmoquine was 30 per cent; but, as this was the first 'general practice year', it is not unreasonable to suppose that this figure may improve with familiarity and experience.

3. Atebrin-plasmoquine also effects a remarkable reduction in relapse rates. This reduction, as noted in 1933-34, was not so striking as that referred to in paragraph 1 above, but it was more marked than that referred to in paragraph 2. This is of some interest because the conditions under which the trial was made fell midway between those mentioned in paragraphs 1 and 2; that is, they were not of the strictest, but they were stricter than general practice conditions.

4. Although there is no great difference in results, still it seems as if the treatment accorded to a group receiving atebrin over seven days was more efficacious than the treatment administered to a group which received atebrin for five days.

These results secured a place for atebrin on the official list of drugs.

The routine treatment of malaria in the Army in India is now based on the following scheme:—

I. Benign tertian malaria

(a) Quinine, 20 grains, with plasmoquine, 0.03 gramme, daily for 21 days; or

(b) Atebrin, 0.3 gramme, daily for 7 days, followed by plasmoquine, 0.03 gramme, daily for 5 days.

II. Malignant tertian malaria

(a) Treatment by quinine, as the case indicates, with a course of plasmoquine (0.03 gramme for 5 days) during convalescence. If necessary (*d.g.*, if crescents be found in thick smears) a repeat course of plasmoquine may be given later; or

(b) As in I (b) above.

Medical officers are, however, allowed much latitude in dealing with this form of malaria, and are encouraged to adopt more drastic measures whenever clinical conditions indicate a severe form of the disease.

III. Quartan malaria

As in I (b) above.

Indian patients are also treated as described above, except that they receive only two-thirds of the British dose of plasmoquine, *viz.* 0.02 gramme daily, administered in 0.01 gramme doses, morning and evening.

After careful consideration it was decided to abolish the Malaria Treatment Centre at Kasauli from the end of the financial year 1933-34. This decision was arrived at because, owing in large measure to the methods of treatment which have been built up on the results obtained at this centre, the type of malaria case with which it was mainly concerned had practically ceased to exist. The centre therefore came to an end chiefly because of the success of its own efforts.

Tuberculosis.—There were 46 admissions for pulmonary tuberculosis, with 2 deaths, and 49 men were sent home as invalids. The ratios per 1,000 were: admissions 0.8, deaths 0.04 and invalids sent home 0.89. The admission and death rates are an improvement on those of the previous year.

Veneral diseases.—The all-India ratio per 1,000 was 33.4. In 1932 it was 37.7.

The incidence of each member of the group, in ratios per 1,000, was:—

Gonorrhoea, 23.2; syphilis, 4.9; soft chancre, 5.0.

Diseases of the respiratory system.—The admissions under this group were 1,198, giving a ratio of 21.8 per 1,000. In 1932 the ratio was 25.3.

Acute and chronic bronchitis and catarrhal pneumonia accounted for 800 admissions, with 4 deaths and 9 invalidings. There were 113 cases of pleurisy and 47 of laryngitis.

Lobar pneumonia accounted for 142 admissions (2.6 per 1,000) and 11 deaths. The case mortality was 7.7 per cent. In 1932, 3.4 per 1,000 were admitted, with 24 deaths and a case mortality of 12.8 per cent.

Ophthalmology.—The decision to accept Indian recruits suffering from mild trachoma has proved to be a step in the right direction, and the policy is being extended in other ways. Thus, at one time, it was customary to segregate boys suffering from trachoma at King George's Royal Indian Military School, Ajmer, from their healthy comrades. With suitable precautions, this custom has been abolished and no fresh case of trachoma has occurred among the boys.

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL H. C. BUCKLEY, Inspector-General of Civil Hospitals, Bihar and Orissa, is transferred, for the remainder of his term, to the post of Inspector-General of Civil Hospitals, United Provinces, with effect from the date on which he assumes charge of that post, *vice* Colonel A. H. Proctor, D.S.O., granted leave preparatory to retirement.

Lieutenant-Colonel P. S. Mills, Civil Surgeon, Ranchi, is appointed to officiate as Inspector-General of Civil Hospitals, Bihar and Orissa, with effect from the date on which he assumes charge of that post.

Lieutenant-Colonel N. S. Sodhi, M.C., Civil Surgeon, Lahore, is appointed to officiate as Inspector-General of Civil Hospitals, Burma, with effect from the 8th April, 1935, *vice* Colonel C. A. Gill, granted leave preparatory to retirement.

Lieutenant-Colonel K. G. Gharpurey is appointed to officiate as Surgeon-General with the Government of Bombay, with effect from the 18th April or any subsequent date on which he assumes charge until such time as the officer selected to hold the post permanently joins.

Lieutenant-Colonel R. L. Vance, an Agency Surgeon, is posted as Residency Surgeon in Kashmir, with effect from the forenoon of the 1st May, 1935.

Major R. S. Aspinall was appointed Civil Surgeon, Simla West, from the 10th to the 16th April, 1935.

The services of Major G. D. Malhoutra are placed at the disposal of the Government of the United Provinces for employment in the Jail Department, with effect from the 6th April, 1935.

The services of Major R. S. Aspinall, Civil Surgeon, Simla West, are replaced at the disposal of the F. & P. Department, with effect from the 17th April, 1935.

Major H. Williamson, O.B.E., an Agency Surgeon, on return from leave, is posted as Residency Surgeon, Hyderabad, with effect from the forenoon of the 19th April, 1935.

The unexpired portion of his leave is hereby cancelled.

Major J. M. Shah, Specialist in Venereal Diseases for the Bombay Presidency, Bombay, to be Officiating Superintendent, J. J. Hospital and B. J. Hospital for Children, in addition to his own duties, during the absence, on leave, of Lieutenant-Colonel Vazifdar.

The services of Captain B. Temple-Raston are placed temporarily at the disposal of the Government of the Punjab, with effect from the 15th March, 1935.

Dr. S. S. Ahluwalia is appointed as District Medical Officer (on probation) and is posted to the N. W. R., with effect from the 30th March, 1935.

Captain H. S. Waters is appointed temporarily to the post of Civil Surgeon, Simla West, with effect from the 17th April, 1935.

Captain J. C. Drummond, on return from deputation to the Millbank Course, is placed on general duty at the Medical College Hospitals, Calcutta, until further orders.

Captain J. C. Drummond, on general duty at the Medical College Hospitals, Calcutta, is appointed to act, until further orders, as Professor of Clinical Surgery, Medical College, Calcutta, during the absence, on leave, of Lieutenant-Colonel F. J. Anderson.

LEAVE

Major-General H. R. Nutt, K.H.S., Surgeon-General with the Government of Bombay, is granted leave on average pay for 3 months and 27 days preparatory to retirement, with effect from the 18th April, 1935, or any subsequent date on which he may avail himself of it.

Colonel C. I. Brierley, C.I.E., Inspector-General of Civil Hospitals, N.-W. F. P., is granted leave on average pay for 25 days and leave on half average pay

for 7 months and 5 days, with effect from the 3rd July, 1935, preparatory to retirement.

Colonel C. A. Gill, K.H.S., Inspector-General of Civil Hospitals, Burma, is granted, with effect from the 30th March, 1935, leave on average pay for 3 months and 18 days, combined with leave on half average pay up to and including the 11th August, 1935, preparatory to retirement.

Lieutenant-Colonel B. Higham, Chemical Analyser to Government, has been granted, preparatory to retirement, leave on average pay for 8 months followed by leave on half average pay for 17 days, with effect from 27th March, 1935.

Lieutenant-Colonel A. Y. Dabholkar, M.C., Director of Public Health for the Government of Bombay, was granted leave on average pay for 8 months out of India from 1st April, 1935, or subsequent date of relief. He is hereby permitted to convert 2 months of that leave into study leave.

Lieutenant-Colonel R. F. D. MacGregor, M.C., an Agency Surgeon, is granted leave on average pay for 1 month and 29 days, combined with leave on half average pay for 4 months and 2 days, with effect from the forenoon of the 19th April, 1935.

Lieutenant-Colonel B. G. Mallya, Civil Surgeon, Howrah, is granted leave for 1 month, in extension of the leave already granted to him.

Lieutenant-Colonel F. J. Anderson, Professor of Clinical Surgery, Medical College, Calcutta, is granted leave for 4 months, with effect from the 20th May, 1935, or from the date on which he may be relieved, and in continuation study leave for 1 month.

Lieutenant-Colonel M. J. Holgate, O.B.E., Civil Surgeon, Karachi, is granted leave for 4 months and a half, with effect from the 30th May, 1935.

PROMOTIONS

Majors to be Lieutenant-Colonels

P. R. Vakil. Dated 4th April, 1935.

J. L. D. Yule. Dated 7th April, 1935.

M. L. Dhawan. Dated 28th April, 1935.

B. S. Dhondy. Dated 28th April, 1935.

Captains to be Majors

K. M. Bharucha. Dated 13th April, 1935.

K. R. Sahgal. Dated 26th April, 1935.

The provisional promotion to present rank of Major J. McM. Wilder is confirmed and antedated from '28th September, 1933' to '28th March, 1933'.

Lieutenants on probation to be Captains on probation,
Dated 1st August, 1934

J. Brebner.

W. J. Virgin.

H. W. G. Stuntor.

Dated 15th August, 1935.

J. D. Gray, C.M. (McGill).

Dated 20th October, 1934

D. W. Taylor.

Dated 22nd October, 1934

P. H. Addison.

Dated 25th October, 1934

C. U. Wickham.

Dated 5th February, 1935

S. G. O'Neill.

F. I. Doherty.

J. W. D. Goodall.

Dated 13th February, 1935

C. B. Miller.

Dated 23rd April, 1935

D. P. Dewe.

M. G. Leane.

G. E. S. Stewart.

RETIREMENTS

Colonel J. P. Cameron, C.S.I., C.I.E., V.H.S., 15th February, 1935.

Lieutenant-Colonel A. F. Hamilton, C.I.E., 25th March, 1935.

Lieutenant-Colonel J. M. G. Skinner, 14th April, 1935.

Lieutenant-Colonel J. B. Lapsley, M.C., 20th April, 1935.

Notes

THE ROMANCE OF EXPLORATION AND EMERGENCE FIRST-AID FROM STANLEY TO BYRD

THIS is a small book containing brief records of the exploits of the chief explorers the world has known. It has been issued in connection with the Chicago Exposition of 1934 by Messrs. Burroughs Wellcome & Co.

Earlier explorers than Stanley are mentioned, but from the point of view of the purpose of this booklet, which is to advertise fitted medicine chests and first-aid kits, he is the first, for he was apparently the first notable explorer to use one of these chests. It is a remarkable testimonial to the excellence of this equipment that practically every traveller or explorer of note on land, sea and air from the time of Stanley to the present day, whether British or not, has made use of them and all testify to their value.

The book is copiously illustrated with reproductions of good photographs and is well printed on good paper. It is a thoroughly pleasing form of advertisement.

BOVRIL, LIMITED

DIRECT NUTRITIVE VALUE OF BOVRIL.

At the Thirty-eighth Annual General Meeting of Bovril, Limited, held in London on the 7th March, 1935, Lord Luke, the chairman, dealt with the results of the past year and explained the financial position, etc., and the resolutions were duly carried.

SIR JAMES CRICHTON-BROWN'S SPEECH

Sir James Crichton-Browne, M.D., LL.D., F.R.S., paid a high tribute to the efficacy of Bovril as a safeguard against the malnutrition which is responsible for so much ill-health. He recalled how the researches of the late Professor Sir W. H. Thompson, of Trinity College, Dublin, undertaken at the request of the Local Government Board of Ireland, had proved beyond doubt that, in addition to its direct nutritive value, Bovril possessed remarkable powers of promoting the digestion and the assimilation of other foods to which it was added.

Sir James said that without mastication, by virtue of those extractives in which Bovril was rich and which imparted to it its aroma, it increased the salivary flow, activated the gastric secretions, and conduced to the production of those hormones which were now known to be necessary to the maintenance of health. At every stage it ministered to healthy functional activity in the alimentary canal and compensated in some measure for the excess of carbohydrates with deficiency of protein and fats which, in the dietaries of the day, was probably responsible for much malnutrition.

A teaspoonful of Bovril does not seem much, but the nutritive value of foods cannot be measured by their bulk.

SERRAVALLO'S TONIC

THIS is described as a mixture of cinchona and iron in a good quality Marsala wine.

From the numerous testimonials supplied by medical practitioners it appears to be of use in treatment of anæmias of the chlorotic type and is widely used in Europe and to some extent in Great Britain. We have not seen a sample of it but the *Lancet* has analysed it and states that both iron and cinchona alkaloids in sufficient quantity to be of medicinal value are contained in the mixture.

AO TUBERCULIN VACCINE

TUBERCULOSIS vaccine is a preparation of tubercle bacilli originated by Arima, Aoyama and Ohnawa in Osaka, Japan, and licensed by the Japanese Government in 1927. According to the originators, AO is made from tubercle bacilli of the human type. It is sterile, consists of the native protoplasm of the bacilli, is easily absorbed, is completely innocuous, is derived from strongly immunizing strains of bacilli, and has a uniform potency. It is sterile and there is no danger of

infection. As it consists of the native protoplasm of the bacilli, it is able to immunize the inoculated organism in the same way as the organism is immunized by infection with live tubercle bacilli. As it is easily absorbed, it acts quickly as an antigen by causing the production of antibodies in the inoculated organism. The easy absorbability is brought about by the autolytic changes which, during the long cultivation, take place in the bacilli, which are devoid of waxy substances. AO is innocuous, as its use in 400,000 patients in different parts of the world up to the end of 1932 shows. No ill effects have resulted from its administration up to the time of writing. Its potency is constant, as its efficacy is measured by a special immunobiologic method and is expressed in antigen units (AE). The application of AO is three-fold: it may be used for prophylaxis, diagnosis and therapy.

Further particulars can be had from the Sole Agents, T. M. Thakore & Co., 43, Churchgate Street, Fort, Readymoney Mansions, Bombay.

BENGER'S FOOD

We have received the following cable from the *Statesman*:—

'All stocks of Benger's Food in India have been requisitioned by Government authorities for use of earthquake survivors (vide *Daily Mail*, 5th June).

Benger's Food Limited desire to make known that as supplies of Benger's Food in India have been requisitioned by the Relief authorities they are using every effort to replenish stocks with all speed. Fresh supplies of Benger's Food are being despatched to India by every available route.

In the meantime Benger's Food Limited request consideration of the public in this time of emergency should inconvenience be experienced in obtaining Benger's Food'.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A RECORD OF FIVE YEARS' ANTE-NATAL AND INFANT WELFARE WORK ON ESTATES IN MALAYA

By J. G. REED, M.R.C.S., L.R.C.P.

Sungkai, Perak, Federated Malay States

Introduction.—The work here recorded has been carried out on a group of seventeen rubber estates served by a central group hospital and situated on the western coastal plains of Malaya. The majority of the estates are small, the largest

until recent years there has been a steady flow of recruited labour from south India. This may be said to have ceased by August 1930, and it is unfortunate that the acute depression in the industry has rendered figures and conditions not strictly comparable from year to year and has made progress more difficult by reason of financial stringency. A number of coolies are engaged locally and these are controlled so far as possible by medical inspection and rejection of the obviously unfit.

Vital statistics.—Some vital statistics of the group are given in table I. The figures for group D in the last horizontal column are from another group of six estates adjoining the group under consideration and are given for purposes

TABLE I
Vital statistics

	Estates population, monthly average	Deaths	Death rate per mille	Births	Birth rate	Deaths under 1 year of age	INFANT MORTALITY	
							Crude	Corrected
Whole group A Average for 4 years, 1925—28.	5,606	184	33.1
1929 ..	5,761	149	25.9	235	40.8	54	230	..
1930 ..	5,533	117	21.1	261	49.0	41	157	162
1931 ..	4,236	97	22.9	216	50.5	44	204	192
1932 ..	3,348	60	17.9	173	52.0	35	202	182
1933 ..	3,229	54	16.7	161	49.8	25	155	152
Average for 5 years, 1929—33.	4,421	95	20.9	209	48.4	40	190	..
Group B Average for 5 years, 1929—33.	740	13	18.4	44	59.3	6	153	..
Group C Average for 5 years, 1929—33.	786	23	27.5	26	36.2	6	240	..
Group D Average for 4 years, 1930—33.	2,387	40	16.4	119	50.5	13	105	..

being of three thousand acres. The estates nearer the sea are subject to malaria carried chiefly by *Anopheles (M.) sundicus (ludlowi)* breeding on adjacent native-owned land where adequate measures of mosquito control cannot be carried out. Estates situated farther inland are practically free from malaria. The average hospital malaria rate for the group for the five-year period under consideration was 5.8 per cent per annum.

The estate workers are Indians, the great majority Tamils, and a considerable proportion has been settled in the district for many years, a number having been born on the estates, but

of comparison. Similar though rather less intensive ante-natal and infant welfare work has been carried out in this group. The great difference between the two groups of estates is that malaria is not endemic on any estate of group D. It has occurred only in sporadic outbreaks on one estate of this group, where *Anopheles (A.) umbrosus* was the carrier, and the population of the group has not been subjected to the marked deleterious effect on general health which is always the result of endemic malaria, even of moderate intensity, and which usually manifests itself notably in the infant mortality statistics. The average hospital

malaria rate for group D for the years 1930—33 was 4.1 per cent per annum.

The figures for group B are taken from three non-malarious estates and those for group C from three moderately malarious estates. These two groups are referred to more fully when table II is discussed. Groups B and C are included in the main group A, while group D is not.

The corrected infant mortality rate is calculated by taking the number of births in a given year as 75 per cent of those actually taking place in that year plus 25 per cent of those taking place in the preceding year. This gives an approximate correction for migration.

It is unfortunate that complete figures are not available for comparison, for the five-year period before ante-natal and infant welfare work was commenced, but consideration of table I compels realization of the necessity for ante-natal and infant welfare work. In 1929 and 1930 over one-third, and in the following three years nearly one-half of the total number of deaths were of infants under one year of age. In England and Wales in 1930, with an infant mortality of 60, the number of infant deaths was about one-twelfth of the total number of deaths. This divergence can only in part be accounted for by the repatriation of a number of old and decrepit coolies, especially in times of economic depression.

Outline of the work.—Observations were commenced on pregnant women during 1929, and at the beginning of 1931 a card index system was instituted which includes also on each card a monthly record of the weight of the infant until it reaches the age of one year. The card is reproduced here. At present not all the items are entered in every case, but the card is designed to be as comprehensive as possible in order to cover abnormal cases and to allow for scope in development of the work. The observations are recorded in the first instance by the estate dresser if there is one, or, if there is not, by a travelling dresser from the group hospital. All cases with any sign or history of abnormality are brought to the hospital for examination, treatment or admission. With the co-operation of the estate staffs we have had little difficulty with the women, though, as they do not like to come for delivery to a group hospital which may be several miles from their estate, this is not insisted on except in case of abnormality. Further, in the same way we keep in touch with the progress of the infants, who are weighed monthly and brought to hospital when necessary. The advantage of the above arrangement is that the women are continuously under the observation of the same staff for as long as required, both before and after confinement. When a woman passes through subsequent pregnancies there is ready to hand her past history and that of her children. Attention has recently

been drawn to the lack of such continuous supervision in Britain. The work has been carried out without special staff and at very small expense. The chief difficulties encountered are the ignorance and superstition of the coolie, but these can be overcome to a great extent by a tactful subordinate staff with time and patience. Transport too is inadequate. One does not know until it is tried which measure will merely irritate the coolie and which she will readily tolerate, but the impression gained on the whole is that many women come to appreciate what is done for them, while others regard it as a routine of estate discipline.

The obvious weak point in the scheme is the absence of supervision of deliveries in the estate lines. Even where there is an estate dresser, he is not usually called to a confinement case until after the delivery. The coolie does not desire supervision of delivery and the present economic conditions make it difficult to enforce it as a new measure. Efforts to induce women of the coolie class to come to the hospital for elementary training, to enable them to act afterwards as midwives on the estates, have met with no success, nor has the employment of a trained midwife at the hospital proved satisfactory. Nevertheless some such supervision is certainly needed. A first-hand account of the native methods of delivery and care of the puerperal woman and the new-born infant makes startling reading. The subsequent figures in this paper indicate that it is the time shortly before, during and after the confinement which is the critical period for mother and infant. This is not the place for discussion of the relative advantages of the individual estate hospital and the group hospital, but the women can in many cases be induced to come to the former for delivery.

Only a limited number of post-mortem examinations can be performed at the hospital and there are no facilities on the spot for detailed pathological and bacteriological examinations.

Past reproductive histories.—Table II gives the past reproductive histories of 826 pregnant women observed to the end of pregnancy over the five-year period under review. Women going through two pregnancies during this period are included once only. The histories are classified according to the result of the pregnancy under consideration, i.e., live birth, still-birth or abortion. In group B are included the histories given by 131 women from three estates which, for practical purposes, may be considered as non-malarious, the hospital malaria rate for the five-year period averaging 1.8 per cent per annum. In group C are included the histories given by 126 women from three estates which may be considered as moderately malarious, the hospital malaria rate averaging 12.1 per cent per annum. Both of these groups are included also in group A. The hospital malaria rate in group B is identical with the true malaria rate as all cases of malaria from these estates would be

sent to hospital. The hospital malaria rate for group C is rather less than the true malaria rate, as a few mild cases and relapses would be treated on the estates. Unfortunately there was considerable fluctuation in the populations of the estates included in these groups; that of group B varied between 888 in 1930 and 586 in 1933: that of group C between 1,114 in 1929 and 512 in 1932.

Some allowance must be made for the illiteracy of the coolie but the figures in table II have been collected with care and are given for purposes of comparison.

As one would expect, the still-birth and abortion rate is higher in all groups among those women whose present pregnancy ended in a still-birth or abortion than among those whose present pregnancy ended in a live birth.

Clinically, the writer has gained the impression that death of the foetus often occurs in subjects of malaria, even when there is no evidence that the infection has been active for any considerable time.

We find then 12 per cent of observed pregnancies ending in still-birth or abortion, and a

Still-births or abortions ..	21	17	41	1.95	21	51	2	4.6
TOTALS ..	126	..	302	2.40	129	43	13	4.1

Table II shows a combined still-birth and abortion rate, for the pregnancies under consideration, varying from 5 per cent in group B to 17 per cent in group C, the percentage for the 826 women observed being 12. The contrast is not so marked in the case of previous histories of still-birth and abortion, the rate being higher (6.7 per cent) in group A than in group C (4.1 per cent), though very low in group B (2.3 per cent). The explanation of this is probably to be found in the history of the malaria on the estates of group C. Figures are not available but, apart from minor outbreaks, endemic malaria did not occur until after the year 1919, the peak period being about 1926. The invasion of malaria is attributed to interference with drainage by the building of a railway and by the silting up of the coast line.

history of 6.7 per cent of previous pregnancies ending in the same way. These figures are low compared with a history of 14.3 to 18.99 per cent of previous pregnancies ending in abortion only, in groups of hospital cases in various parts of England from 1845 to 1913. These figures are quoted by Feldman (1927).

It is worthy of note that, in the above table, the number of children per woman is 2.40 in group C, 2.31 in group B and 1.88 in group A. The average birth rate for the five-year period is however 36.2 for group C, 59.3 for group B and 48.4 for group A. This would appear to indicate that endemic malaria of moderate intensity has a gradually cumulative effect on fertility. The percentage of children surviving at a given time is seen to be 62 in group B, 43 in group C and 60 in group A.

The figures in table III referring to still-births and abortions are not accurate for the year 1928. They refer almost entirely to those taking place in the hospital, as the system of notification had not been elaborated. It is possible that a few early abortions may have been missed in the later years also.

Maternal morbidity and mortality.—It may be stated at once that the type of case which the ante-natal work was primarily designed to prevent was the woman with profound anæmia and œdema, who usually either aborts or gives birth to a still-born child or a child who is weakly and likely to die shortly after birth. The cause of such a condition in the mother is usually malaria, dysentery or syphilis or a combination of two or more of these diseases. Ankylostomiasis also plays a part, but in spite of primitive sanitation, only some 15 per cent of cases admitted to hospital for all causes were found by simple slide examination to be infested

with hookworms. There is no doubt also a nutritional element in the majority of these cases, and in some no obvious cause for the condition can be found. In this type of case the woman herself commonly survives but becomes a chronic invalid and a heavy expense to her relatives and to her employers for many months.

One would indeed expect ante-natal work in this country to act more beneficially on the infant by way of the mother than in England. Though the fœtus will gain its nourishment at the expense of the mother, women in the condition described above cannot produce such healthy children as normal women.

That some success has been achieved in preventing this type of case is shown in table IV. For the purpose of these observations cases are considered to be anæmic when the hæmoglobin reading on the Tallqvist scale is 50 per cent or less at any period of the pregnancy.

TABLE IV
Anæmia among pregnant women, and maternal deaths

Apparent cause of anæmia				1929	1930	1931	1932	1933	TOTAL
Malaria	11	22	11	5	3	52
Malaria and syphilis	6	2	1	1	..	10
Syphilis	4	2	1	2	..	9
Helminthiasis	5	1	4	10
Amœbic dysentery	1	2	3
No obvious cause	7	8	2	2	..	19
TOTAL ..				28	34	20	12	9	103
Cases per cent of live births ..				11.9	13.0	9.3	6.9	5.6	9.9
Maternal deaths ..				5	2	2	1	1	11

Of the 41 cases occurring in the years 1931 to 1933, one woman died undelivered and 12 had still-births or abortions, 29.2 per cent of conceptions thus terminating. Of 29 living children, seven or 24.1 per cent died. The average birth weight of ten of these children was 4.5 pounds against an average of 5.3 pounds for 50 unselected new-born infants.

There are no facilities for detailed blood examinations but the impression gained clinically is that true pernicious anæmia of pregnancy is rare, and the majority of cases appear to be of the secondary, microcytic, hypochromic type usually responding with greater or less rapidity to treatment of the primary cause and, in addition, massive doses of iron and, in some cases, marmite. In some cases the hæmoglobin percentage may oscillate very rapidly from month to month, and in a few there is a very rapid fall shortly after delivery.

For ankylostomiasis, oil of chenopodium is given in three doses of five minims each at hourly intervals. Pregnant women tolerate this dosage well. Atebrin is given for malaria with good results. Syphilis is discussed later.

The maternal mortality rate is undoubtedly high but many of the deaths occurred several weeks after childbirth and could not be attributed solely to it. In many cases death was due to several co-existing diseases. According to Briere-Lefebvre (1933) the maternal mortality rate for Ceylon in 1932 was 19.2 for the whole island, 31.3 for the urban areas. Luddington (1933) states that for Indian labourers on estates in Ceylon the rate was 20.4 in 1931, 17.2 in 1932. This rate is reported to have been declining somewhat rapidly since 1930 and is said to refer to mothers dying at childbirth. The maternal mortality rate for the group of estates under consideration for the five-year period was 29.6 with a maximum of 46.2 in 1932 and a minimum of 18.6 in 1933. The causes of the maternal deaths were as follows:—

Malaria and complications	9
Puerperal sepsis	8
Dysentery and anæmia	2
Dysentery and sepsis	3
Post-partum hæmorrhage	2
Acute diarrhoea	2
Hemiplegia	1
Nephritis	1
Cirrhosis of liver	1
Rupture of Cæsarean scar	1
Hyperemesis gravidarum	1

TOTAL 31

Labour is usually easy and malpresentations are not common. During the five years 64 cases were admitted during labour. These included: delayed labour and uterine inertia, 43; retained placenta, 5; eclampsia, 6; contracted pelvis, 3; transverse presentation, 2; malaria, 2; œdema, amœbic dysentery and bronchopneumonia, 1 each. In addition 125 patients were admitted in the ante-natal period, and 41

in the post-natal, making a total of 230 or 21 per cent of the women observed. Outpatient treatment was given to 164 women.

The average pelvic measurements of 100 women were: interspinous diameter 8.6 inches; intereristal diameter, 9.5 inches; difference, 0.9 inches. The average birth weight of 50 infants was 5.3 pounds.

Abortions, still-births and neo-natal deaths.—The term abortion is taken to mean the expulsion of a dead foetus at any time before the twenty-eighth week of pregnancy; the term still-birth means the expulsion of a dead foetus after this time; and the term neo-natal death means death of the infant before the age of four weeks. It is difficult in many cases to be certain of the exact period of gestation in these women, so that a few abortions and still-births may be wrongly classified.

Table III shows that the annual abortion rate has considerably decreased while the still-birth rate has actually increased. Further work will be needed before the tendency of the neo-natal and infant mortality rates can be clearly defined. The still-birth rate in Ceylon has also remained high while the infant and maternal mortality rates have shown a tendency to come down.

Multiple births.—Mention may be made here of the appalling mortality experienced among multiple births. Out of nine sets of twins and one set of triplets, a total of twenty-one individuals, occurring in the five-year period, there were two still-births, sixteen neo-natal deaths and two infant deaths, only one individual surviving. Although the mortality among twins is always higher than among single births, this experience must have been peculiarly unfortunate as twins are not uncommonly met with among estate populations.

Consideration of table V and the chart following it justifies the following deductions. The infant mortality rate of the group of estates is high compared to the ante-natal mortality which itself compares well with that of western countries, especially in the case of abortions. Even the still-birth rate of the group of estates compares well with that of the urban areas of Ceylon and with that of Indian mill-workers. In this connection the fact that the still-birth rate of mill-workers is nearly double that of the wives of workers is worthy of notice. Many estate coolies cease work two months before delivery is expected and very few work during the last month of pregnancy. Special attention has not been given to this point, and, although the work of estate coolies is probably of a more healthy nature than that of mill-workers, being almost entirely out of doors and not very strenuous, the matter is one that should be kept in view and the date on which the woman ceases work should be noted on the ante-natal card.

The proportion of infant mortality to total mortality is high in the group of estates, as is

Ceylon, 1932		29.2	Turner (1933).
1929-33	41.7		

the proportion of neo-natal mortality to total infant mortality. In both cases the proportion tends to be higher in eastern countries than in the west, but in both cases the proportion recorded for the group of estates is high even for eastern countries.

Arthur Robinson quoted by Feldman (1927) estimates that inherent defects in ovum or spermatozoon are responsible for 40 per cent of total prenatal fetal mortality in human beings. This factor might be expected to act mainly during the earlier months of gestation and in many cases the condition would be described clinically as sterility. There is no evidence that this factor plays any disproportionate part among the race and castes with which this paper is concerned.

Table VI shows abortions, still-births and neo-natal deaths classified, so far as possible, according to their primary causes. Under the

heading 'syphilis' have been included group I, cases with Wassermann and Kahn reactions positive and group II, cases with Wassermann and Kahn reactions doubtful or disagreeing. These groups are referred to again when table VIII is discussed. It has not been possible to find any group of figures strictly comparable to those of table VI, but in table VII the percentages of still-births and neo-natal deaths have been compared with certain groups of figures quoted by Christine Thomson (1930) in her paper, *Still-birth and Neo-natal Death in India: A Preliminary Enquiry*. The writer is greatly indebted to this work. Thomson states that this is a field of enquiry which is virtually unexplored, and indeed her work must be a model for future investigators. Unfortunately it was not published until some time after the work here recorded was commenced, nor was it immediately available to the writer.

Chart to show comparative numbers of abortions, still-births, neo-natal deaths and infant deaths per 1,000 live births in:—I. Western countries; II. The group of estates under consideration, 1930–33; III. Thirty-six towns of Ceylon, 1932; IV. India, 1927. Column I is of a composite nature, the figures below the line being from an estimate calculated by Feldman, those above being the figures for England and Wales in 1925. The full figures for the towns of Ceylon and for India are not available.

The figures in column 2 of table VII refer to a series of 200 post-mortem examinations of urban hospital cases. The cases are not consecutive and still-births largely predominate, numbering 169, 85 being macerated, while 153 of the 200 cases were premature, post-mortem examinations on very premature foetuses being more readily obtained than those on full-term children. The figures in column 3 are from part II of Christine Thomson's paper, which refers to an All-India Questionnaire. From this the writer has abstracted the figures referring

to 979 urban hospital cases from Madras, the Presidency from which come the majority of the workers on the group of estates under consideration. Thomson states that, in the absence of detailed pathological and clinical data, figures referring to syphilis will be an under-estimate and those referring to prematurity *per se* and to neo-natal disease must be scientifically unreliable. In this Madras series there were 622 still-births, 138 being macerated, and 355 neo-natal deaths: in two cases the condition was not stated. In table VII the writer has transferred the item 'complications of labour. Normal labour (cause unknown)' to the heading 'cause unknown'. The figures in column 4 are from a series of 1,311 cases, an average for five British cities, examined by Holland and Lanc-Clayton (1926). The heading 'post-natal causes' has, for various reasons, been omitted by these authors, although neo-natal cases dying from other primary causes are included.

Consideration of table VI shows that in the group of estates malaria, anaemia and syphilis are the most common causes of abortion. There has been a considerable reduction in all these diseases in the later years of the period under consideration. Malaria also figures largely as a cause of still-birth while neo-natal states are the most important cause of neo-natal deaths. It must be remembered that but few post-mortem examinations could be made and therefore complete accuracy cannot be claimed for the figures of table VI. Browne (1922) has called attention to the frequency of cerebral haemorrhage among premature infants even when delivery is easy; also to the fact that an infant at birth may be suffering from advanced pneumonia, a common cause of post-natal death. An acute haemorrhagic form of pneumonia may cause sudden death.

Table VII shows the figure for the group of estates for the complications of labour to be very low. The figure 25.3 per cent for this cause for Madras is the lowest in the total of 3,708 cases from all India, the figure amounting to 50 to 60 per cent or more for cities in northern India where osteomalacia is common. The writer has found accidental haemorrhage and placenta praevia to be uncommon and could attribute no death to these conditions. The figures for the group of estates for syphilis, prematurity *per se* and neo-natal disease are all high while that for toxæmia of pregnancy is low. No deaths could be attributed to congenital malformations or foetal disease.

Nutrition.—One cannot escape the impression that malnutrition of the mother is the underlying factor in many cases of premature birth and foetal and neo-natal death. The Tamil dietary is deficient in vitamin A, in fat and in animal protein. Xerosis, nyctalopia and pyorrhea are all found not uncommonly, though it

cannot be said that they are specially common among pregnant women.

The strain of the later months of pregnancy seems to render the mother highly susceptible and more vulnerable to common tropical diseases

such as malaria and amœbic dysentery, which often become manifest shortly before or after delivery. Malnutrition also appears to play a large part in the causation of anæmia and œdema. True beri-beri is almost unknown

among these women, but œdema is very common with any debilitating disease such as malaria or amœbic dysentery. It may occur in the absence of such diseases and may or may not be associated with anæmia. Œdema of the vulva and deeper tissues favours difficult labour, perineal tears and local sepsis. The treatment of œdema may prove very difficult. The dividing line between œdema of nutritional origin and that of nephritic or toxæmic origin does not appear to be clearly defined. Cases have been observed of œdema without albuminuria in the later months of pregnancy, in which albuminuria appeared for the first time during or shortly after labour. Treatment of the underlying disease, if any, combined with the administration of alkalis and attention to diet and nutrition helps these cases but is not always entirely satisfactory.

Facts which support the impression that malnutrition of the mother plays an important part in foetal and neo-natal mortality are the low average birth weight (5.3 pounds) of infants, and the very heavy mortality among multiple conceptions which must throw an added strain on the mother. Deficiency of fat in the maternal diet will tend to the production of children of low birth weight. It has been established by Margaret Balfour (1930) that the death rate in the first three months of life is very much higher when the birth weight is low, being 62 per thousand for babies with birth weight of 5 to 5½ pounds, 333 for those with birth weight of 4 to 5 pounds, and 840 for those with birth weight below 4 pounds.

An attempt was made to estimate the state of nutrition of a number of women by the *pelidisi*, an index of nutrition calculated from a formula involving the weight, the sitting height and the estimated intestinal area. Such an index cannot of course be applied to pregnant women. An index of 90 is said to indicate a low state of nutrition, an index of 100 a normal state of nutrition and an index of over 100 and up to 113 a fat person. The index was calculated for 41 apparently healthy women. The average *pelidisi* was 98, maximum 107, minimum

88. The average weight of the same women was 88 pounds, maximum 110 pounds, minimum 68 pounds. For any definite conclusions to be drawn it would be necessary to calculate the nutritional index before or after pregnancy of large comparable groups of women who had on the one hand normal infants and on the other abortions, still-births or premature or sickly infants.

According to Wills and Talpade (1930) working in Bombay, lack of vitamin B in the maternal diet may cause the birth of premature infants. Deficiency of vitamin E (similar in constitution and physical properties to vitamin A) by leading to inherent weakness in the germ cells is said to be a factor in the causation of premature births as well as early abortions. McCarrison (1929) states that deficiency of vitamin A in the mother's diet may be a cause of infant mortality by causing weakness of the child at birth. Hypothyroidism associated with low blood pressure is said to predispose to still-birth by favouring the onset of toxic conditions. In some cases habitual abortion is said to be connected with increased venous pressure which may be treated by intermittent digitalization and administration of pituitary extract and subsequent oral calcium. For recurrent abortion a diet is indicated which is rich in vitamin E with the addition of iodine, calcium and possibly corpus luteum. For this condition potassium iodide in minute doses with Bland's pill has been advocated even if the Wassermann reaction is negative. For repeated still-births ten grains of calcium lactate twice daily from the sixth month of pregnancy has been advised and the writer has used this treatment in a few cases.

Syphilis.—Frank syphilis of either the congenital or acquired variety is not common among the estate population. However it appeared desirable to investigate the prevalence of the disease and, through the kindness of the Director of the Institute for Medical Research, Kuala Lumpur, it was possible to have a number of Wassermann and Kahn tests carried out. The results of this investigation are given in table VIII. These cases must be regarded as

TABLE VIII
Results of Wassermann and Kahn reactions, and past reproductive histories, 1929—33

Groups	Number of women	Per cent of total	PREVIOUS CHILDREN		PREVIOUS CHILDREN ALIVE		PREVIOUS STILL-BIRTHS OR ABORTIONS	
			Number	Children per woman	Number	Per cent of previous children	Number	Per cent of total previous pregnancies
Group I, W. and K. positive	40	23	61	1.53	21	34	25	29
Group II, W. and K. doubtful or disagreeing.	43	24	75	1.74	21	28	20	21
Groups I and II ..	83	47	136	1.64	42	31	45	25
Group III, W. and K. negative	94	53	214	2.28	91	43	44	17
TOTALS ..	177	..	350	1.98	133	38	89	20

selected and the chief reasons for which the tests were carried out were, a pregnancy ending in still-birth or abortion or a history of such, neo-natal deaths or a history of such, a family history of syphilis, and in a few cases anaemia not responding to ordinary methods of treatment. In some cases the tests were not made until after the termination of the pregnancy under consideration. Women who went through more than one pregnancy during the five-year period or who had their blood tested on more than one occasion are included once only in these tables.

Group II, Wassermann and Kahn reactions doubtful or disagreeing, is made up as follows:—

W. ++, K. —	, 1	W. ±, K. —	, 12
W. +, K. ±	, 4	W. —, K. +	, 2
W. +, K. —	, 3	W. —, K. ±	, 3
W. ±, K. ++	, 2	Others	1
W. ±, K. +	, 2		
W. ±, K. ±	, 13	Total	43

There is little doubt that the great majority of cases in this group are syphilitic.

On comparing table VIII with table II, taking groups I and II of table VIII together, we find that 83 selected cases out of a total of 826 women or 10 per cent had serological evidence of syphilis. The percentage of still-births and abortions in past histories is much higher in all groups in table VIII than in table II, being 25 per cent in groups I and II and 17 per cent in group III of table VIII. The percentage of children surviving at a given time is low in table VIII, being 31 per cent in groups I and II and 43 per cent in group III, against 60 per cent of those born to the whole number of 826 women.

Table IX shows the results of the pregnancies undergone by these 177 women during the five-year period under review.

those without. There are more of both abortions and still-births in the group of cases with negative Wassermann and Kahn reactions. Contrary to what would be expected, the number of abortions is greater in all groups than the number of still-births. The neo-natal mortality is however much higher in the group with evidence of syphilis. In this connection the effects of treatment must be considered, and also the fact that even the case with negative Wassermann and Kahn reactions had for the most part been selected on account of a history of still-births or abortions. The infant mortality, high in all groups, is much higher in the group with evidence of syphilis, in spite of treatment. Treatment would appear to be more effective in preventing still-births and abortions than in preventing neo-natal deaths.

The results of treatment are analysed in table X. The first results with intravenous arsenicals were unfortunate. Of the first two cases, one aborted on the day following the first injection and the other died a few days after an injection, with signs and post-mortem findings suggesting encephalitis hæmorrhagica. This naturally prejudiced the women and a trial was made of a method similar to that advocated by Dr. and Mrs. A. R. Cook (1929) in Uganda. A mixture containing a thirty-second of a grain of mercury perchloride and a sixty-fourth of a grain of methylene blue in an ounce of water was given twice daily for as long a period of the pregnancy as possible. Dr. and Mrs. Cook found that in Uganda few women showed active signs of syphilis, while abortions, still-births, and congenital syphilites were very common. Many women who had had a long series of miscarriages bore healthy children for the first time after a course of this 'blue mixture', often given throughout pregnancy. If the mother showed signs of active syphilis, one

Table IX shows the foetal mortality to be lower in cases with evidence of syphilis than in

or two salvarsan substitute injections were given in addition. The results obtained with this

treatment on the group of estates were also encouraging; the mixture costs practically nothing and is surprisingly popular among the coolies, the blue colour apparently attracting them. Later, treatment with arsenicals was cautiously resumed, blue mixture being often given as well. Intramuscular stabilarsan was used on occasion and the present policy is to give a minimum of three injections of stabilarsan, with blue mixture for as long as possible. In some cases bismuth or mercury is given in addition. Great caution is certainly necessary in the administration of intravenous arsenicals to pregnant Tamil coolie women.

In table X, group I includes cases treated with at least three injections of arsenicals, with or without mercury, bismuth or blue mixture in addition. In some cases it was possible to give six injections of arsenicals. Group II includes cases treated with blue mixture alone for three months or more. Group III includes all cases who either received no treatment at all, often because the blood was not tested until after the termination of the pregnancy, or less than three injections of arsenicals and/or less than three months' treatment with blue mixture. This group is considered to have received no treatment. Table X includes the cases of groups I and II of tables VIII and IX.

The figures in this table are certainly small, especially in group II, but they are definitely in

Table XI includes the number of deaths, the percentage of the total number of deaths and the mortality per 1,000 live births for each age group for each year. Some figures for England and Wales for 1921 and for the U. S. A. for 1919 are included for comparison. In the case of England and Wales the percentage of the total number of deaths and the mortality per 1,000 live births is given for each age group; in the case of U. S. A. only the mortality per 1,000 live births.

Table XI shows a very high mortality rate for the group of estates for the first day, week and month of infant life, especially the latter. The mortality for these three periods of infant life is especially low in the two years 1930 and 1933 in which the total infant mortality is low. The probable effect of malnutrition of the mother on early neo-natal mortality has already been discussed. There is a definite tendency for the mortality rate to come down in the latter age periods, three to six and six to twelve months. This is the usual experience in infant welfare work.

Table XII is concerned with the final causes of infant mortality and this explains why only three deaths are attributed to syphilis. The chief causes of death are seen to be developmental conditions and the miscellaneous group 'other conditions', among which convulsions

favour of those receiving treatment, and the results with blue mixture appear to be better than those with arsenical injections. The opinion gained is that blue mixture is definitely of value and that there is justification for persisting in its use.

In a very few cases it is possible that children may have left their estate and died subsequently, but the great majority were kept under observation.

Infant mortality is classified in table XI by age groups, and in table XII by diseases and disease groups.

bulk large. The majority of deaths from developmental conditions are dependent on ante-natal influences of which malnutrition of the mother is probably the most important. The mortality for developmental conditions is considerably lower in 1933 than in any other year. There is a definite tendency for the mortality to come down in the group 'other conditions'. The mortality from bowel diseases is low, probably because the great majority of infants are still breast-fed. In western countries the greatest reduction in infant mortality is found in diseases of the digestive system and in

convulsions which, according to Feldman, may also be caused by unsuitable or infected food.

Convulsions.—From experience of the limited number of post-mortem examinations on infants which it was possible to make, the writer is of the opinion that some cases of convulsions were due to bronchopneumonia which was found post mortem in a number of cases reported as dying from convulsions. In such cases the death was entered under the heading bronchopneumonia. This disease can at times kill with appalling rapidity. It is not uncommon to obtain a history that a child was bright, cheerful and feeding well in the morning and was dead by the afternoon, and to find typical bronchopneumonic patches in the lungs on post-mortem examination. This may also occur with older children. Some cases of convulsions were probably due to syphilis. Brownlee (1918) states that convulsions are a reflex phenomenon, due to a variety of intoxications, alimentary or otherwise, and that their occurrence is an index of the condition of the nervous system at each point of growth, the essential factor in their causation being nervous instability. Brownlee's opinion is that consideration of convulsions as a symptom rather than a disease is not justified. He states that the death rate from this cause decreases smoothly with age.

It is logical to deduce from tables XI and XII that attention to the condition of the mother before confinement is probably the most important factor in preventing infant mortality. Every effort must be made to build up her strength by inducing her to take a suitable diet and by supplementing it with such additions as can be made, such as milk and cod-liver oil. All cases who show signs of incipient disease, malnutrition or anemia must be admitted early to hospital. It is important also to ensure that facilities are provided for the mother to look after her child adequately on the estate, and to feed it at regular intervals. Regular examination of infants and their early admission to hospital if the weight does not increase satisfactorily will also save a number of lives.

Summary and conclusions.—Five years' ante-natal and infant welfare work on a group of rubber estates is recorded, complete figures being only available for the last four years. The writer is very conscious of the defects of this paper. Full scientific investigation of cases was not possible as the work was carried on without special staff, as part of the routine of estate practice. But estate practice does give the opportunity for continuous investigations on a population subject to a considerable degree of control, and these findings are put on record in

the hope that others, perhaps more fortunately situated than the writer, may bring forward observations in a field that has been but little touched in the past, and which, if fully explored, cannot fail to yield information of practical value.

Certain deductions are justified. One of the most important is that endemic malaria, even of moderate intensity, plays a very large part in foetal mortality and maternal morbidity and,

less directly, in neo-natal mortality. This is made clear in many ways throughout the paper. The effect is much greater than would be made evident in the usual health statistics supplied by estates.

Maternal mortality is high, being largely due to intercurrent disease, but considerable success has been met with in the prevention of the anæmia so often met with in pregnant women of the class under consideration.

The abortion rate compares well with that of western countries, and a still-birth rate of 5.1 per 100 live births is a satisfactory figure for an eastern country. Malaria and anaemia are the most common causes of abortion, and syphilis is of importance in the causation of abortions as well as of still-births and neo-natal deaths. In comparison with western countries the proportion of still-births and neo-natal deaths that can be attributed to complications of labour, toxæmias of pregnancy and ante-partum hæmorrhage is low while neo-natal states bulk large in this respect.

Infant mortality is responsible for the large proportion of 41 per cent of the general mortality while neo-natal mortality accounts for no less than 56.8 per cent of infant mortality. The average weight of new-born infants is low, being 5.3 pounds, and, although it is difficult to prove statistically, there is much evidence to suggest that malnutrition of the mother is responsible for a large proportion of foetal and neo-natal mortality.

The results of the investigation of the Wassermann and Kahn reactions of a number of pregnant women are given and the relation of these to foetal and neo-natal mortality is discussed. The effect of treatment on these cases is analysed and some success with mercury perchloride by mouth is recorded, caution being necessary in the use of arsenicals.

Ante-natal influences are seen to have a large effect on infant mortality and many findings point to the great importance of care of the mother during pregnancy and labour. The difficulties incident on supervision of labour have not yet been surmounted.

It is difficult to make a final assessment of the value of the work since figures are small and the time period short and no figures are available for populations, otherwise comparable, among which no such work has been carried out. Nevertheless results have been sufficient to provide encouragement for continuation of the work.

Acknowledgments.—The writer wishes to record his gratitude to assistant surgeons A. Devasagayam and T. Mahadevan. Without the interest, skill and sympathy shown by the former in dealing with women of an uneducated class, the work could never have been initiated. The latter has carried on the work and has been of great assistance in collecting statistics. Thanks are indeed due to all the hospital and estate staffs for their ready co-operation and interest and to others for their advice and encouragement, especially to Dr. A. Neave Kingsbury, Director of the Institute for Medical Research, Kuala Lumpur, and the staff of the Institute who carried out the serological examinations.

INVESTIGATIONS ON CEREBRO-SPINAL FEVER IN NASIRABAD (RAJPUTANA) DURING THE PERIOD 1931 TO 1934

Part I

By E. A. R. ARDESHIR
CAPTAIN, I.M.S.

Officer in charge, Brigade Laboratory, Nasirabad

I. Introduction

In this paper, I shall confine myself chiefly to the epidemiological and preventive rather than to the clinical aspect of cerebro-spinal fever, and describe the measures which resulted definitely in controlling the disease.

Cerebro-spinal fever is confined only to one unit stationed permanently at Nasirabad, i.e., the 10/6th Rajputana Rifles, which is a training

battalion. The function of this unit is to procure new recruits, and to train them for a period varying from 9 to 12 months, before sending them away to the five active battalions of the group. Besides the recruits, the number of whom varies from 400 to 500, the battalion consists of a permanent staff of about 400 men employed as instructors, lecturers, clerks, schoolmasters and artificers, who remain in the station for a period of two years or more. The battalion, on an average, recruits 300 new men yearly from Jaipur, Jodhpur, Bikaner and other Rajputana States, and also one hundred men from the Punjab. In the Rajputana States, cerebro-spinal fever is known to be prevalent sporadically.

Cerebro-spinal fever was detected for the first time in Nasirabad in December 1927, when two cases were reported. Since then, there has been a gradual but very steady and perceptible rise, year by year, culminating in a local epidemic with 15 cases in 1930, nine of which occurred within one month.

TABLE I

Annual incidence of cases, since 1927

Year	Cases	Deaths	Case mortality
1927 ..	2	1	50 per cent
1928 ..	7	1	14 "

'Carrier' test on non-contacts commenced November 1931.			
1932 ..	1	1	75 per cent
1933 ..	4	3	
1934 ..	1	1	
TOTAL ..	47	26	55 per cent

The method adopted to control the fever from 1927 to October 1931 was to search for 'carriers' amongst the contacts of cases, after the fever made its appearance. When I took over the charge of the brigade laboratory at Nasirabad, in October 1931, after a review of the whole situation, I realized that little was being done bacteriologically to prevent the disease till actual cases of the fever appeared.

I, therefore, decided that to check the disease effectively and to prevent its recurrence, as many carriers as possible should be detected and isolated before the disease made its appearance. With this view, to begin with I decided to search for carriers in the permanent staff, who, having constantly to shout at, or lecture the recruits, were most likely to spread the disease. During this period, each individual

was examined to see if he were a carrier, for six consecutive days. Though the number of carriers identified and isolated from amongst this group of men was small, this method met with instantaneous success, as the case incidence dropped from 17 in the year 1930-31 before it was adopted to 2 in 1931-32, the following year.

The next step taken further to control the disease was to examine the entire battalion for carriers. This work was taken in hand from November 1932 to March 1933. It was soon apparent that if every man of the battalion was examined for six consecutive days, the time required, the labour entailed, and the cost of material would be enormous. Besides, with increasing experience and better organization, it was observed that it was possible to detect a large majority of carriers at one of the first three swab examinations. So after this, every man was examined thrice, and during the season 1933-34 this was further reduced to two examinations.

II. Mode of introduction of cerebro-spinal fever in 10/6th Rajputana Rifles at Nasirabad

No case of any form of meningitis has been recorded prior to 1927 in the troops stationed at Nasirabad, so it may be assumed that cerebro-spinal fever made its appearance for the first time in that year. The disease could only be introduced from one of the three following sources:—

- (1) From the civilian population of Nasirabad.
- (2) From the recruits entering the battalion.
- (3) From the permanent members of the staff of the battalion.

The first is very unlikely, as from 1927 to 1933 not a single case of meningitis has been seen in the Cantonment General Hospital at Nasirabad, which deals with about 60,000 cases per annum. Hence, the disease could only be introduced by either the recruits entering the battalion, or the permanent members of the staff of the battalion. This question, which had remained a moot point for years and was the cause of advancement of various theories for and against, was not finally settled till the completion of investigations carried out by me and my two assistants from November 1932 to March 1933.

To settle the problem once for all, a large number of men were examined to see if they were carriers amongst the members of the permanent staff of the battalion, and similar examinations were carried out among the recruits; and it was soon found that the percentage of carriers in the permanent staff was much higher than the percentage in the recruits. A recruit technically means a new entrant to the battalion up to a period of 9 to 12 months. Therefore, it was further necessary to isolate

the new entrants to the battalion, and to examine them within 10 days of their arrival at Nasirabad.

1. Three hundred and seventy-five recruits kept isolated and examined within 10 days of their arrival gave a carrier rate of 1.8 per cent.
2. Four hundred members of the permanent staff examined gave a carrier rate of 44 per cent.
3. Recruits leaving the battalion after a period of 9 to 12 months showed a carrier rate of 22 per cent.

Therefore, the natural conclusion derived from these investigations was to the effect that the disease was conveyed by means of carriers to the incoming recruits, from the permanent members of the staff of the battalion.

A few more facts may be mentioned which show that the disease could not be introduced by the recruits entering the battalion.

1. The disease, while occurring amongst the civilian population of the recruiting area of the battalion, is not prevalent to such an extent as to attract attention.

months after their arrival at Nasirabad, i.e., after they have come in contact with the permanent members of the staff who show a disproportionately higher carrier rate.

III. The mode of propagation of the disease within the unit

The above facts leave but scant doubt that the disease, having been introduced into the unit in 1927 for the first time, is kept up by carriers (permanent, temporary or intermittent) who mostly belong to the permanent staff, and to a lesser extent by the recruits who are infected later by the old carriers.

IV. Aetiology

1. Age

As the preponderating number of cases is amongst the recruits, the age incidence is naturally low; the youngest age being 16, the oldest 26, and the average 19.2.

2. Sex

The sex question arises only in so far as there are about 350 women and children residing

CHART I

23	..
24	..
25	1
26	1
Total	47

2. As far as it is possible to ascertain, no similar outbreak of cerebro-spinal fever has occurred in other training battalions which recruit from the same area.
3. The incubation period of cerebro-spinal fever being from 3 to 10 days, it is but reasonable to expect that a few cases would occur in the recruits immediately on arrival at Nasirabad, but this has never happened. On the contrary, the disease in a large number of cases makes its appearance in recruits three

permanently in the unit family lines; no case has ever occurred in the families, though carriers were isolated from amongst the men of these lines, and the standard of spacing of beds in the families is not on such a generous scale as that of men in the regular barracks.

3. Length of service of cases in the station

By far the largest number (about 30 per cent) of cases occurred in the third month of the recruit's entrance into the army. It is considered that this is due to the fact that the third month is the most difficult and strenuous portion

of his training; this, no doubt, lowers his resistance to infection and also recruits enrolled during September and October have their most strenuous training period coinciding with the two most rigorous and trying months of the year (December and January) when a very large number of cases of nasal and respiratory diseases occur, which, as will be seen later, are associated with the incidence of cerebro-spinal fever (see chart V).

CHART II

Showing number of cases according to length of service in station

4. Susceptibility of various classes of men to disease

Of the total 47 cases, 38 (i.e., 80.8 per cent) occurred amongst the recruits, the remainder being shared by the followers and men of the permanent staff in the proportion of 12.8 and 6.4 per cent respectively.

This disproportionate number of cases amongst the recruits becomes more marked when it is considered that they harbour comparatively few carriers amongst them. The number of recruits affected with the fever is still further increased if five of the six followers, whose service in the battalion ranges from eight days to five months, are included amongst the recruits as they should be, in consideration of the shortness of their service. It is noteworthy that age and recent entrance into the battalion play an important part in the causation of disease at Nasirabad.

5. Seasonal incidence of cases

Saligman, in Prussia, finds the highest incidence of cases in the first half of the year, decreasing about the middle, and lowest in autumn and winter months. Thus his March records are highest and those of December lowest. In Nasirabad, however, cerebro-spinal fever is a disease of the winter and spring months, by far the greatest number of cases (82.8 per cent) occurring then; while the remaining 17.2 per cent, distributed in the summer seasons of 1929-30, 1933 and 1934, are more in the nature of exceptions than the rule.

TABLE II

Case incidence of 6-monthly period from November to April (winter and spring)

TABLE III

Incidence of cases from May to October (summer and monsoon)

Season (May to October)	Number of cases	17.2 per cent cases in summer and monsoon months.
1927 ..	Nil	
1928 ..	Nil	
1929 ..	4	
1930 ..	2	
1931 ..	Nil	
1932 ..	Nil	
1933 ..	1	
1934 ..	1	
TOTAL ..	8	

A perusal of tables II and III and chart III shows at once that, as opposed to Saligman's finding, our cases begin to occur between September and November, reach the peak between December and February, and begin to fall rapidly every month, finally ending in June, and that there is a definite lull in occurrence of cases between April and September; during this period very few carriers are found even after repeated throat-swab examinations.

CHART III

Showing monthly incidence of total cases from 1927 to 1934

This is quite in keeping with the observations of Fildes and Baker, who investigated the cerebro-spinal fever outbreak in the British Navy during the years 1916 and 1917. They observed their first case in October and the second in November. From this time onwards the cases increased almost weekly, reaching a climax about the end of February. After this date the number of cases declined to zero. They further record a smaller secondary rise in May and June. This also has occurred, to a lesser extent, in May at Nasirabad. Hence it will be apparent that seasonal incidence in this station approximates very closely with the English figures, as worked out by Fildes and Baker, and is opposed to Saligman's findings in Germany.

6. *Effect of temperature*

The lower the temperature the greater the risk of cases occurring, and the appearance of cold bleak winds, even for a day or two, was always looked upon by us as ominous; consequently, during the five months from November to March, one lived in almost constant dread of the sudden appearance of the disease. It is perhaps not fair to blame entirely the cold wave, because severe cold leads to the very unhygienic habit amongst the recruits of herding in barracks, and causing coryza, throat and respiratory diseases, which lower the resistance and render them susceptible to the effects of meningococcus.

7. *Humidity*

Compton, working in Egypt and also in the British Isles, lays great stress on the relation between the relative humidity of the air and the occurrence of cases. He records a case that developed cerebro-spinal meningitis after being in a hot bath for over an hour, inhaling the heavily vapour-laden atmosphere of the room. It is even suggested that by observing the humidity charts it may be possible to predict the occurrence of cases. This point was investigated by me as it was apparent that in a dry, sandy and barren place, devoid of lakes and rivers, like Nasirabad, this factor could hardly play as important a rôle as it would in places like Egypt and England.

Note.—Chart for the year 1932 is not appended as only one case was reported during the 12 months. Here again very great similarity exists between it and those of the previous years. Humidity during the month of December, in which the case occurred at humidity 57, was generally much lower than the two rainy months of July and August.

Official records of the humidity of the air, previous to the year 1930, are not available, but, as the largest number of cases have occurred during 1930 and 1931, these years could be

considered to form a fair average. For reasons of space, the humidity charts per month have not been included, but it is obvious that in Nasirabad the humidity factor has no connection whatever with production of cases. The above charts indicate that the majority of cases occur much below the curves of the most humid months (July and August) of every year. All over India humidity is highest during the rainy season, Nasirabad being no exception. If humidity was an important factor, one would reasonably expect more than the 17 per cent of cases that have occurred during the most humid period from May to October (*see table III*).

As the unit is in occupation of eighteen blocks of barracks and as cases have been noted independently from various buildings at various times, it was not possible to keep an accurate record of the actual internal humidity conditions of each one of them; but if, as Compton states, internal humidity is dependent on external atmospheric conditions, then, in my opinion, this factor played an unimportant rôle in this station. It is, however, remotely possible, that the comparatively humid conditions within the old barracks may have been a contributory factor in the production of a large majority of cases and carriers in these barracks. In this station the men of this battalion are housed in two entirely different types of quarters—the old and the new buildings. The old ones are narrow, low-roofed and dark, decidedly admitting less sunlight, and allowing but little free interchange between outside and inside air. The new type have more doors and windows, are without dark corners, and above all have good stone-paved flooring. This is in marked contrast to the old barracks, which have mud floors covered with *lipoid* (a mixture of horse-dung and sand).

8. *Relation of cases to old and new barracks*

All the cases, except two, have come from the old type barracks and a very large proportion (80 per cent) of carriers have for years been lodged in them. It is, therefore, clear that the interference with free circulation of air and sunlight, together with the *lipoid* floors and the very pernicious habit of the men of spitting in and around the corners of the buildings, have materially helped in carrying on the disease from one season to another, through the medium of its unduly high percentage of carriers.

9. *Effects of fatigue*

It has not been possible to find a practical method of gauging accurately the effects of fatigue, but considering the significant fact that 30 per cent of total cases appeared during the third month of the recruits' service—the period associated with the most strenuous time in the training—it suggests that this cannot be a negligible factor, and that it plays a part of great

importance in production of cases. It is held that change of environment and occupation due to transfer from civil to military life, the fatigue incidental to military training, and the association with the permanent members of the staff of the battalion infected with micro-organisms, have been important factors at Nasirabad.

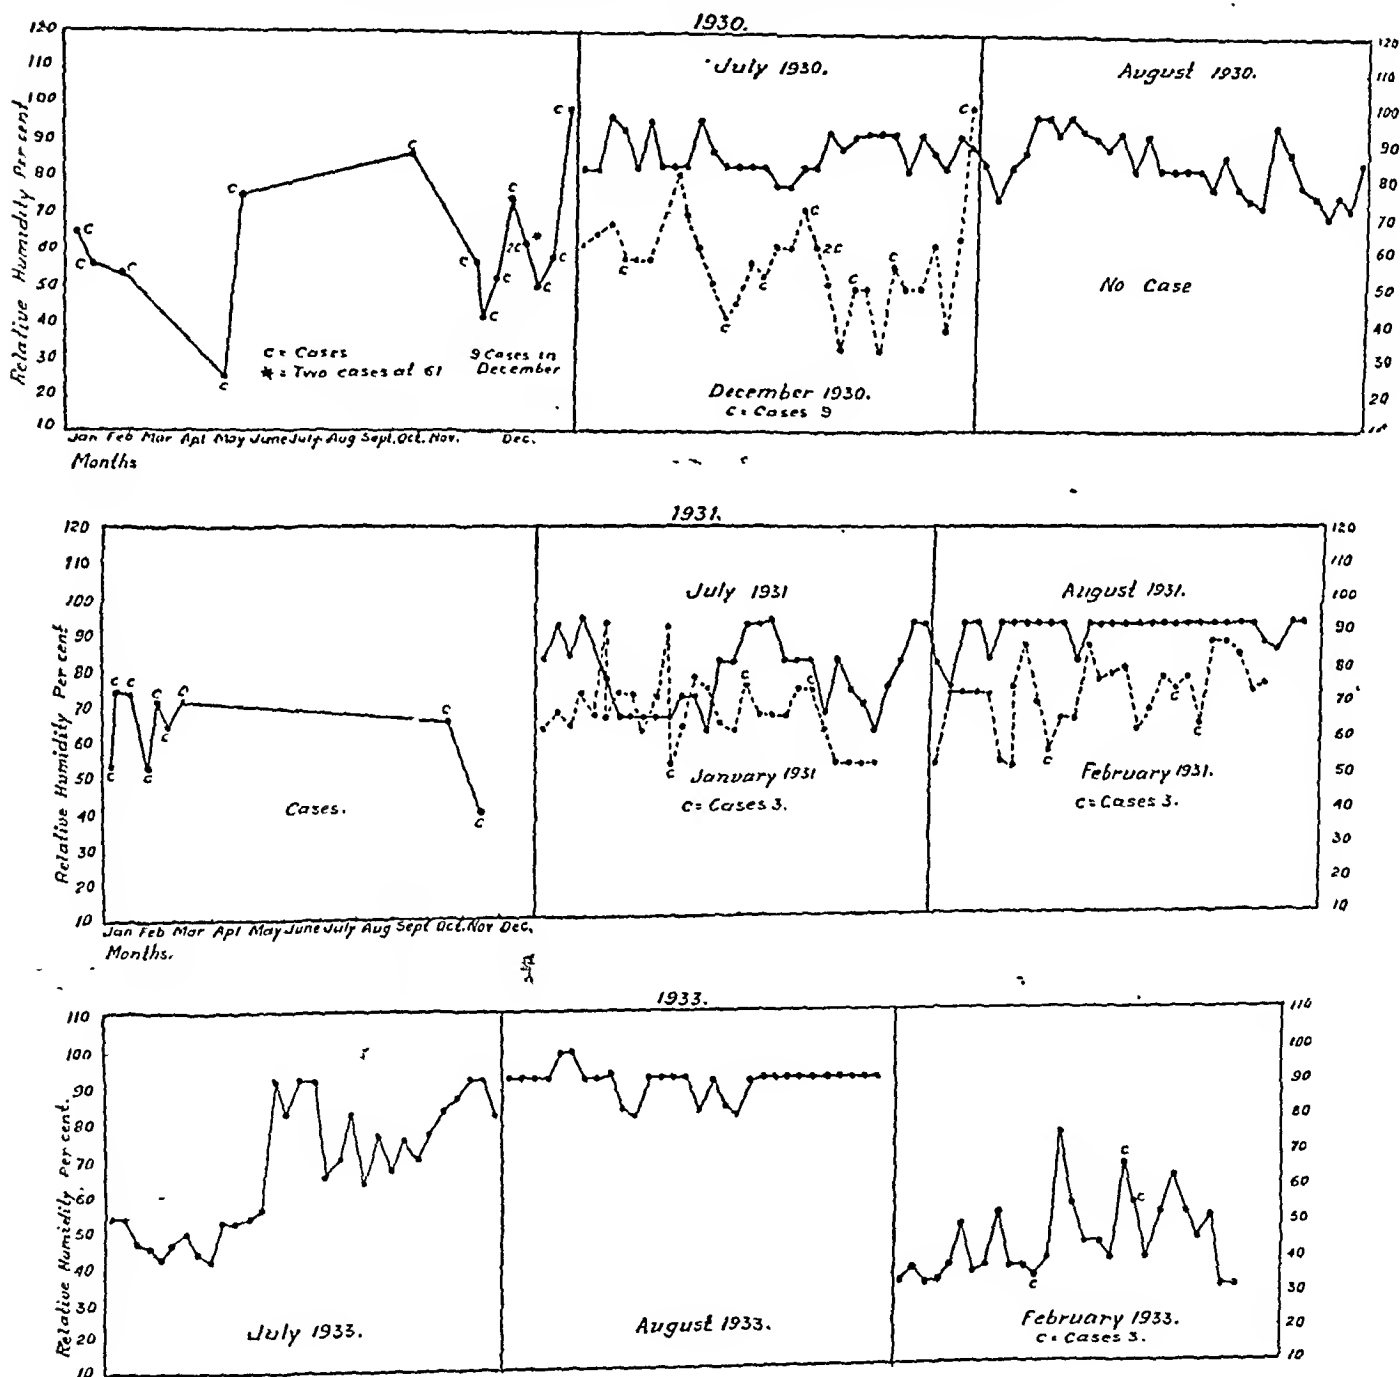

of cases in the third month of their service remains unaccounted for.

10. Overcrowding

Overcrowding, from the point of view of military standards, either in barracks, or within the unit area, has always been associated with

CHART IV

Showing incidence of cases and their relation to outdoor atmospheric humidity, during the years 1930 to 1934, and comparing with the most humid months of the year

It seems that the repeated and persistent occurrence of cerebro-spinal fever cases in the numerous training battalions, in various countries, becomes explicable by this hypothesis. Should the fatigue factor be entirely unconcerned in precipitating the disease in susceptible recruits, the occurrence of over thirty per cent

occurrence of cases. There was evidence of overcrowding within the barracks, during the outbreak of December 1930 (when we had 9 cases). Again in February 1933 three cases were admitted to hospital within a week, while the battalion was in the midst of its 'regimental reunion', a quinquennial function associated

with a fortnight's gaiety and feast making, when some 550 extra men were entertained in Nasirabad. Though 250 were lodged in a special camp, the remaining 300 had to be accommodated in the barracks and all available buildings. Here, once more, temporary but definite overerowing was apparent.

11. Relationship between cases and prevalence of respiratory diseases

It has long been observed that the predominant number of cerebro-spinal fever cases and carriers are found during the time that respiratory diseases of mild pathogenicity, such as coryza, pharyngitis, influenza, and bronchitis, are most prevalent. This factor by encouraging sneezing, coughing and generally increasing the 'spraying capacity' of carriers is an important predisposing cause. It is also likely that these diseases by lowering the vitality make them more prone to infection by the meningococcus.

CHART V

Showing total monthly admissions for nose, throat, and respiratory diseases (1927 to 1934) and comparing with cases of cerebro-spinal fever

From the above chart it will be seen that the largest number of cerebro-spinal fever cases occur between December and February, and the rate of admission for nose, throat and chest diseases is also highest from November to January. A closer relationship between the two diseases is established if the entire black curve is shifted one month forwards. It will then be noticed that the peaks of both coincide extremely closely. It can therefore be assumed that it takes about a month for the effects of the increase in respiratory diseases to be reflected in occurrence of cases of cerebro-spinal fever.

Summary

1. The disease was checked in a most striking manner immediately on isolation of carriers.
2. It was not introduced repeatedly, as had previously been thought probable, by fresh batches of 'new entries', whose carrier rate was found to be only 1.8 per cent.
3. Though very-large numbers of carriers were found among the permanent staff, they suffered least from the disease.
4. The recruits, while showing few carriers, were most affected. Contrary to expectation,

(Continued at foot of next column)

INFECTIVE WARTS AND THEIR TREATMENT

By L. M. GHOSH, M.B. (Cal.), D.T.M. (Liverpool) and

P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
(From the Medical Mycology Inquiry, under the Indian Research Fund Association)

WARTS, excluding the senile or seborrhœic type, are usually divided into the following four varieties:

1. *Verruca plana seu juvenilis*.—These are usually small and vary in size from that of a pin's head to one or two millimetres in diameter. They occur most often on the backs of the hands, but are also common on the face, especially the beard region and forehead, and occasionally they are found on the scalp and trunk.

2. *Verruca vulgaris* or the common wart.—These are also known as vegetative warts. They are longer than the plane variety and are papillomatous in character, and although they may be as small in diameter as the above type and filiform, sometimes they are as large as half an inch in diameter.

3. *Verruca plantaris*.—These are horny, corn-like growths usually on the soles of the feet but sometimes on the palms of the hands. They do not project much externally but their inward projection into the corium may be considerable. They are often mistaken for corns but differ from the latter by the possession of blood vessels.

4. *Verruca accuminata*.—This type occurs mostly in the folds about the genitals and anus, and is probably always of venereal origin.

In this paper we only deal with the first two varieties.

Ætiology.—Many theories as to the causation of these growths have been put forward, but

(Continued from previous column)

new entrants were singularly free from disease. Only one case occurred among approximately 2,000 new recruits that joined the battalion since 1927. [This statement appears to us to be contradictory. Presumably the writer means that only one recruit developed the disease subsequent to his arrival but within the incubation period of the disease.—EDITOR, I.M.G.]

5. When the carrier rate in the general population rose to 14 per cent cases began to occur.

6. Very close relationship is established between occurrence of cases and overerowing, prevalence of respiratory diseases, winter season, period of training, and the age of the recruit.

7. Humidity of air had no bearing on the production of the disease.

[The paper sent to us by Captain Ardeshir is too long for publication in *extenso* in this journal. The parts omitted deal mainly with the bacteriology and technique. We hope to be able to publish a summary of this portion at some future date.—EDITOR, I.M.G.]

until the researches of Wile and Kingery (1919) and Kingery (1921) were published indicating that a filtrable virus was probably the causal factor none appeared satisfactory. This theory is now generally accepted by dermatologists.

Treatment.—As the theories of the ætiology of warts were numerous so also were the methods of treatment recommended. For instance, amongst others Bloch (1927) claimed cures by auto-suggestion, Dietel (1928) and Duprat obtained good results from protein shock, Sezary (1928) employed hæmotherapy with varying success, Laurie (1932) advocated bismuth salicylate injections, and Sutton (1927) claimed that arsphenamine was a cure.

The number and variety of treatments recommended is sufficient indication that none can be very satisfactory.

Biberstein (1925) was the first to suggest treatment of warts and condylomata by the injection of an autolysate, and he reported a cure rate of 75 per cent of his cases, in some instances having to give as many as forty injections to effect a cure. Cormia (1934) used Biberstein's method but reported unfavourably upon it. Most of Cormia's cases were of the 'vulgaris' type, and our results, which are given below, offer a possible explanation of this worker's non-success.

Encouraged by the success attending the treatment of a series of molluscum contagiosum cases by injections of an autolysate (Ghosh, 1934) we decided to try similar treatment in the case of warts.

Preparation of the autolysate.—The warts are sterilized by the application of alcohol, and ether in equal parts. They are then carefully removed so that no normal skin is included in the portion cut off. A known weight (in this instance 20 mgm.) of wart tissue is ground up in a sterile agate mortar with sterile pumice-stone powder until it forms an uniform emulsion when mixed with sterile normal saline solution. The amount of saline used for the above quantity of wart tissue is 20 c.cm.

The mixture is placed in an incubator at 37°C. for 24 hours and is then filtered, first through a Kieselguhr filter and afterwards through a Chamberland candle no. L. 3, under negative pressure.

A quantity of saline containing 0.25 per cent commercial formaldehyde and equal in amount to the filtrate is added to it.* The filtrate is

now tested for sterility, and if found to be free from bacterial contamination it is ready for use.

Dosage.—The initial injection for adults was 0.2 c.cm. of the filtrate prepared as described above. Subsequent doses were increased each time by 0.2 c.cm. until 1 c.cm. was reached after which no further increase was made. The injections were given subcutaneously or intracutaneously twice weekly. From the case abstracts in the table it will be seen that as few as six injections effected a cure, and twelve injections was the greatest number given in any case.

It was found that plane warts responded readily to treatment, and if not cured rapidly they at least improved very much, but warts of the papillomatous type did not respond at all to autolysate injection and cleared up with injections of a bismuth preparation given intramuscularly.

Both forms of warts are held to be produced by the same infecting agent, the vegetative type only being an advanced stage of the plane variety so it was decided to try and discover by histological examination why one type responded to treatment and the other did not. Warts of both types were removed and sectioned and these were examined by Dr. M. N. De, Professor of Pathology at the Medical College Calcutta, whose report is given below.

Report of Dr. De

Type 1. *Verruca plana*.

The principal changes in this type are confined to localized changes in the skin.

Verruca plana.

(1) Hyperkeratosis of the horny layer is present in varying degrees in different sections, but in none of them is it so well marked as in the papillomatous type.

(2) There is a marked thickening of the corium and hyperplasia of the epithelial cells almost obliterating the connective tissue of the papillae. The epithelial prolongations are seen to penetrate deeply into the sub-epithelial tissues instead of being heaped up outwards as in the papillomatous type. The inflammatory cellular exudates and dilatation of blood vessels are

* In the treatment of molluscum contagiosum Ghosh (1934) used formalized autolysate with a strength of 0.2 per cent formalin, but on account of the pain it caused a change was made to carbolyzed autolysate. The latter, however, did not appear so efficacious. In treating psoriasis Panja and Maplestone (1935) abandoned formalized autolysate for the same reason as the above and got good results with carbolyzed autolysate. In the present instance it was found that reducing the strength of formalin to one-half lessened the pain of the injections and yet it was of sufficient strength to keep the solution sterile.

TABLE
Plane warts

Case number	Caste and sex	Age in years	Duration of disease	Distribution	Number of injections	Result	REMARKS
1	M., M.	30	2 years	Face, forehead and temples.	8	Cured	After fourth injection was away a month, and given another 4 injections on his return.
2	H., M.	20	2 months	Face, temples and neck.	6	Cured	No relapse for one year.
3	M., M.	17	3 months	Face and scalp.	7	Cured	Lysate from case 2 used.
4	M., M.	48	1 year	Face and trunk.	7	Cured
5	Jew, M.	31	1 month	Scalp and forehead.	6	Cured	Fresh warts appearing at first. None after third injection; all gone after sixth injection except 2 large horny warts which were cauterized with CO ₂ snow. Lysate from case 2 used.
6	H., M.	26	..	Chin, neck, fingers and toes.	5	Cured	Cured by 4 injections; one more given. Lysate from case 2 used.
7	M., M.	28	3 months	Face	7	Cured	First 3 injections from case 1. Last 4 autolysate. Discontinued treatment without orders.
8	E., F.	35	..	Extensor surface arms.	10	Much improved.	After 6 injections much improved, stopped coming for a month. Given 4 more injections, not seen again, but had improved further.
9	H., M.	50	2 years	Face	8	Cured	A few vegetative warts also present removed with CO ₂ snow. Lysate from case 2 used.
10	H., M.	7	5 years	Face, scalp, body and legs.	12	Almost cured.	Very extensive warts still appearing at beginning of treatment. Dose reduced as follows: first 0.05, second 0.1, third 0.2, fourth 0.3, fifth 0.5, sixth 0.5 and up to eleventh dose 0.5, twelfth 0.6 c.cm. Still under observation; no relapse.
11	A.-I., M.	22	..	Hands, body, face and legs.	4	Much improved.	Did not come after fourth injection.
12	M., M.	28	4 years	Face and chin.	11	Cured

TABLE—concl'd.
Papillomatous warts

Case number	Caste and sex	Age in years	Duration of disease	Distribution	Number of injections	Result	REMARKS
13	H., M.	18	2 years	Dorsum of foot.	8	No effect	First and second injections from case 1. Third to eighth autolysate.
14	H., M.	25	2 years	Under chin and neck.	10	No effect	Eight injections of autolysate and 2 from case 1. Cured by 6 intramuscular injections of bismuth.
15	H., M.	44	2 years	Face and neck.	8	No effect	Autolysate. Subsequently cured by 8 injections of bismuth.
16	H., M.	20	..	Scalp and face.	6	No effect	Three injections lysate from case 7. Three injections lysate from case 14.
17	A.-I., M.	26	6 months	Face	10	No effect	Subsequently cured after 6 injections of bismuth.

Abbreviations.—

M. M. = Mohammedan male.

H. M. = Hindu male.
E. F. = European female.

present in varying degrees in sections from different cases.

Type 2. Verruca vulgaris.

Verruca vulgaris.

These are typical papillomatous outgrowths from the skin. The papillae are very much elongated and are covered by heaped-up squamous epithelial cells. The

interpapillary connective tissue shows slight inflammatory reaction but marked vascularity. The amount of cornification is very well marked and in the horny layer clumps of melanin were seen.

Conclusion.—Whatever the ætiology of these two types of warts may be they appear quite different histologically and their evolution and growth are not alike.

This report suggests that the difference in structure and direction of growth may explain the different reactions to treatment. It is possible that the plane warts which burrow deeply into the corium are more readily acted upon by substances circulating in the blood than are the papillomatous type whose main growth is outwards.

The principal differences between these two types of warts are well shown in the accompanying photomicrographs.

Summary

The treatment of 17 cases of infective warts by injection of an emulsion made from wart tissue is recorded.

The method of manufacturing the emulsion is described.

Twelve cases of plane warts were treated with remarkably good results, and in five cases of papillomatous warts the same treatment proved quite ineffective.

A report on the comparative histology of these two types of warts is given, and this offers

SNAKE VENOMS IN PHARMACOLOGY AND THERAPEUTICS

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

J. S. CHOWHAN, M.B., B.S.
CAPTAIN, A.I.R.O.

(From the Department of Pharmacology, School of
Tropical Medicine, Calcutta)

(Indigenous Drugs Series No. 56)

THE knowledge regarding snakes and the effects produced by their venoms dates back to the remote past. The symptoms produced by snake venom and the different remedies applied to relieve its effects have formed the subject of study by the ancient peoples. Folk-tales about the peculiar symptoms produced by snake venom in man and the wonderful after-effects of sublethal doses are many and venoms have been regarded as a panacea for many incurable diseases by even those practising the healing art. In fact the snake has become an ideal of the art of healing, magic and authority in Greek mythology. The emblematic figures of Asklepios as an old man reclining on a staff with snakes coiling around it and his sister

Hygieia as a woman holding a snake in one hand and a bowl in the other are well known. The Roman mark of healing 'caudeceus' is represented by flying wings attached to a staff with a pair of snakes coiling around it. Brahma, the Hindu God of creation, has been shown as guarded by the 'Sheshanag', a legendary snake with many heads. Shiva, the Lord of Destruction, has been shown with coils of snakes around his neck. The cobra by virtue of having the mark of 'omega' on its hood has become an idol of Hindu worship in many parts of India.

Strong poisons like snake venoms which produce potent physiological effects and marked constitutional symptoms, if given in mitigated and reduced doses, may produce desirable therapeutic effects. During the last decade attempts have been made to study these therapeutic effects in various diseases and to give a scientific explanation of how they are produced. In this paper we propose to discuss, first the pharmacological action of the venoms of various snakes met with in India and then give an account of their uses in therapeutics.

The pharmacological action of snake venoms

Venom when fresh is a transparent and clear fluid. It is faintly acid in reaction and its consistency varies from that of water to the thickness of the white of an egg. Cobra venom is a transparent, amber-coloured or almost colourless fluid having a specific gravity of 1.110. It is acid in reaction and slightly disagreeable in taste. Crotalus venom varies from a pale to an emerald green and orange or straw colour. It has no taste and its specific gravity varies from 1.030 to 1.044. The venom rapidly becomes alkaline in reaction on account of the disappearance of a volatile acid during decomposition. When dried under a bell jar on concentrated sulphuric acid or in the sun, it loses about 50 to 70 per cent of water and is converted into a yellowish scaly mass and can be easily powdered. If kept in hermetically-sealed ampoules and in a cool dark place it keeps its potency for a long time. The toxic principles of the venom reside in albumins which are thermostable, and a coagulable proteid which is thermolabile. The former is in excess in the cobra and is called 'neurotoxin', and the latter is in excess in viper venoms and is called 'hæmorrhagin'. The viperine venom contains another substance called 'thrombase', which causes intravascular clotting. The specific action of venoms, in short, appears to depend upon the ferments and the lysins they contain. As far as is known, the following substances mainly enter into the composition of the venom—fibrin ferments, proteolytic ferments, cytolytic cells, nerve cells and agglutinins, and neurotoxin having a selective action on all the nerve tissue, especially in the respiratory and vasomotor

(Continued from previous page)

a possible explanation of their varying reactions to treatment.

Acknowledgment

We wish to express our thanks to Dr. M. N. De for the trouble he took in examining our material, and for his histological report which is incorporated in the paper.

centres. The toxic effects of different venoms are briefly stated in the table below :—

and white 'spectacle' marking on the hood (seen when fully spread) and a black and white

TABLE I (after Rogers and Megaw, 1935).

Class	Nervous system	ON BLOOD AND BLOOD VESSELS		
		Hæmolysis	Coagulation	Hæmorrhages
Hydrophidæ (sea snakes) ..	Paralysis of respiratory centre and muscular system.	Very slight	Slight reduction	Nil
Colubridæ (cobras) ..	Do.	Moderate	Nil	Nil
Viperinæ (true vipers) ..	Paralysis of vasomotor centre.	Pronounced	Intravascular clotting, later incoagulability.	Very pronounced
Crotalinæ (pit vipers) ..	Do.	Do.	Intravascular clotting less pronounced, in coagulability pronounced.	Do.

As regards the action of different venoms on man it has been observed that the neurotoxin in cobra venom has a special affinity for the respiratory centre and for the neighbouring ganglia of the 9th, 10th, 11th and 12th cranial nerves, and a curara-like effect on the motor end-plates of the muscles. The krait neurotoxin has a selective action on the anterior horn cells of the spinal cord.

Phisalix and Pasteur (1928) noticed that animals vaccinated against rabies were refractory to the action of venom of the cobra and viper and *vice versa*; in other words the virus contained an antigen both for rabies and for the venoms. It has been further shown that the exposure of the venom of *Vipera aspis* to ultra-violet rays does not diminish its virulence but increases it in certain cases. The ultra-violet rays however destroy the antirabic power of the

spot on either side of the lower surface of the hood. This form is more commonly found in southern India and Ceylon. There are several varieties in India without hood markings.

Acton and Knowles (1914) found that an adult cobra of 4 feet 2 inches injects about 211.3 mgm. of the venom at a single bite, while the M. L. D. of cobra venom for man of 60 kilogrammes is about 15 mgm., causing death in three hours (see table II). This shows that the cobra generally injects about 10 to 15 times the M. L. D. In the case of a common krait about 5.4 mgm. is injected at a single bite. The M. L. D. for monkeys is 0.15 mgm. and for a man it is estimated to be 1 mgm., it therefore injects about 5 to 10 times the M. L. D.

Chopra and Ishwariah (1931) investigated in detail the pharmacological action of the venom of the Indian cobra (*N. naia*) and reported that

TABLE II
Showing M. L. D. for different types of snakes

Snake	Approximate dose at a single and good bite	M. L. D. for rat	M. L. D. for monkey	Estimated fatal dose for man
Common cobra (<i>Naia naia</i>) ..	211.3 mgm.	0.12 mgm.	2.4 mgm.	15.0 mgm.

(Quoted from Byam and Archibald)

venom. A temperature of 100°C., although it destroys the toxin and the antivenomous properties of the viper venom, does not produce any effect upon its rabicidal properties.

The venom of the Indian cobra.—A large example of *Naia naia*, the Asiatic cobra, is six feet in length. The coloration of the typical form is yellowish to dark brown with a black

the M. L. D. of this venom varies with different kinds of animals. It is relatively less toxic to frogs, cats and rats but fatal to dogs, rabbits and men. When injected intravenously the venom produces immediate fatal effects. If the dose is large, the animal dies within a few minutes from respiratory failure. The venom being colloidal in nature, its absorption is slow

if injected hypodermically or intramuscularly and hence the symptoms are much delayed and death may be delayed from 4 to 24 hours. When given by the mouth the venom is not absorbed by the intact mucous membrane and does not produce any marked toxic effects. It has been shown that the venom is identical with the salivary secretion, and is a digestive enzyme. It does not affect the activity of the salivary, gastric and pancreatic secretions of man *in vitro*, though it slightly increases the muscular tone of the gastro-intestinal tract in cats and rabbits. Sublethal doses produce a small but persistent rise in the blood pressure in experimental animals. The rise is not due to the stimulant action in the accelerator mechanism of the heart or the action on the myocardium. In experimental animals no concentration could produce any definite stimulation or reviving effect on the failing heart. Large doses appear to act directly on the heart muscle and produce depression followed by cessation of its movements. The rise of blood pressure appears to be due to the temporary stimulation of the vasomotor centres. The subsequent marked fall of the blood pressure is due to late paralysis of the vasomotor centres. The main action of the venom is on the respiratory centre which is initially stimulated, then paralysed. Histopathological studies of the brains of cobra-poisoned mice by Scharenko showed that the toxin paralysed the vasomotors; this was followed by a local stasis and subsequent corresponding necrosis.

It has no action on the motor end-plates of the diaphragm and other muscles involved in the mechanism of respiration. The action of the venom is exclusively on the nervous mechanism and this was demonstrated by Chopra and Chowhan (1931) by a detailed study of its action on protozoa. It was observed that the venom of the Indian cobra is toxic to protozoa. The paralysis of the movements of *Paramœcium caudatum*, which appears to possess a rudimentary neuro-motor apparatus, by cobra venom is confirmatory evidence of its selective action on this organ. It was further shown by them (1932) that the venom of Russell's viper, which is poor in neurotoxic principles, does not produce any effect on the activity of the movements of *P. caudatum*. The action of this venom is mainly on the endothelial cells of the vascular system and, as these protozoa have no organized vascular system, they are immune to the toxic action of viper venom, while the animals which have a well-developed vascular system are severely affected by this venom.

The venom of the Indian daboia and other vipers.—These vipers are considered to be next to the cobra in the order of their toxic action. The most important Indian pitless viper, called the daboia or *Vipera russellii*, is locally known as 'Uloobora' or 'Tic-polonga'. The other important viper is *Echis carinata* also known as the saw-scaled viper, 'Phoorsa' or 'Kupper'.

The daboia is found in all parts of India, Ceylon, Burma, Siam, Sumatra and Java, whilst the saw-scaled viper is frequently met with in the N. W. F. P., Sind, Rajputana, Central India, Madras and Ceylon. Vipers (commonly called adders) are found under various conditions, in open woods where there are slopes and gullies exposed to the sun, on heaths and moors. Heaps of loose stones or tumbled walls are favourite prowling places and hunting grounds for food. Like the American rattlesnake and copper-head they prowl into the farms during the late summer, when the grain has ripened, in search of small rodents and are often discovered under sheaves or thrash piles. In the mountains they occur up to elevations of at least five thousand feet. They return to specific places to hibernate, but in congregating at their dens in the autumn they are not so easily seen, as they hide under the early fall of leaves where their body hue and pattern blend with the ground. The small size of the viper enables it to work its way through comparatively small holes.

The venom of the Indian daboia is a clear orange-coloured oily fluid having a specific gravity of 1.077 and when dried it yields orange-coloured scales or masses. There has been considerable doubt regarding the action of viper venom. Wall and Cunningham were the first to study the action of cobra and viper venoms. Mitchell and Reichert showed that the intense local irritant action and the sense of burning pain felt after the bite of a viper is due to the large quantity of globulin (as much as 25 per cent) present in it, while the albumoses, which are responsible for the nervous symptoms, are present only in very small quantities. Viper bites lead to severe pain, abscesses, gangrene and often multiple hæmorrhages and later to ascending paralysis of the central nervous system. Lamb and Hanna made some observations on the properties of the Indian daboia venom. Rogers working on the antidotes of colubrine and viperine venoms recorded that a small dose of Russell's viper venom intravenously should kill by a rapid fall of the blood pressure without any intravascular clotting, but with a loss of coagulability. This condition could always be produced by injecting a sublethal dose while a large lethal dose produced a fatal circulatory failure. He proved, by cutting the spinal cord, and by direct observations on the portal circulation, that the essential cause of death was paralysis of the vasomotor centre, the heart continuing to beat to the end. The African puff adder, the American rattlesnake and the Indian pit vipers, all produce death in the same manner so that vasomotor paralysis is the main action of viper venoms and, in addition, there is a hæmorrhagic effect which is most marked in the case of the rattlesnake. It has been shown that daboia venom contains a hæmorrhagin which destroys the endothelial cell-lining

of the finer blood vessels and consequently gives rise to ecchymosis and extravasation of blood, and the convulsions seen early in viperine poisoning are due to small hæmorrhages in the cerebral cortex, a cytolytic which dissolves the red blood corpuscles and a fibrin ferment (thrombase) causing intravascular clotting, pulmonary embolism and death from asphyxia. The slow and delayed symptoms after injection of the venom are due to its remaining localized. The fatal dose for a monkey of 25 kilogrammes weight is 7.5 mgm. and for man the M. L. D. is 42 mgm., death occurring in 24 hours. The average dose given at a single bite is about 72 mgm., which is more than double the minimal lethal dose. Crimmins (1931) stated that the diamond back rattlesnake of Texas may discharge 9 to 40 lethal doses of the venom at one bite. In the case of the echis the M. L. D. for a monkey is 0.5 mgm. and for a man is 5.0 mgm. and the approximate dose of the venom injected at a single bite is about 12.3 mgm. (Acton and Knowles, 1914). Here also the snake injects almost double the fatal dose. Chopra and Chowhan (1934) investigated the pharmacological action of the venom of Russell's viper, and found that the hæmorrhagic phenomena appear at the outset of poisoning and are very extensive in character. Death is preceded by spasmodic and irregular respiration, convulsions and asphyxia indicating the involvement of the vagal centre owing to deficient blood supply. In all post-mortem examinations recorded, the lungs show symptoms of asphyxia, petechial hæmorrhages and infarctions. The right side of the heart is full of dark blood and the left side is empty and tonically contracted. In frogs the venom produces less harmful effects. In animals which have died of daboia poison the kidneys show inflammation, mottling of the cortex and extensive hæmorrhages. The serous cavities such as the pericardium, the pleura and the peritoneum are full of sanguineous fluid, probably produced by injury to the delicate endothelial cells of the capillaries, leading to excessive leakage of the blood.

The daboia venom has a marked tendency to produce thrombosis and gangrene at the site of the bite and death is due to secondary shock. The systemic blood vessels, especially the peripheral ones, are found to be contracted and those of the splanchnic area are widely dilated, as in histamine shock. That the nervous centres are not much affected is shown by the fact that in decerebrated animals exactly the same results are produced. If the action is prolonged, these measures are of no avail since the normal relative permeability of the vessel walls to the protein constituents of the blood is lost. Capillary leakage goes on to such an extent that anything injected leaks out of the vessels. The symptoms of shock in daboia poisoning are not due to reflex impulses, but to the local dilatation of the capillaries of the

splanchnic area. The paralytic action of the venom seems to be confined to the capillaries only and is similar to histamine.

In the case of lachesis, Vellard and Vianna (1932) found that intramuscular and subcutaneous injections in dogs produce an initial incoagulability by rapid destruction of fibrinogen and of the complement by the protease of the venom; subsequently there is absence of formation of thrombin due to the action of the venom on the hepatic cells and hæmolysins are also increased. After intravenous injection there is at first intravenous clotting, followed by incoagulability of the blood in about five minutes. It was further shown that, while the venoms of lachesis and trimeresus are anti-complementary, cobra venom has less and slower anti-complementary action and crotalus has no action on the complement at all. A certain incubation period precedes the anti-complementary action. Malcolm Smith and Hindle found that the M. L. D. (for mice) of the venom of the pit viper (*Trimeresus sumatranus*) and *T. vagleri* to be 0.5 mgm. and 2.45 mgm. per kilo. body weight, and that of the sea snake (*Latecauda colubrina*) to be 0.113 mgm. but they doubt that the total yield of the venom for any of these three species is sufficient to render the bite dangerous to a healthy adult person.

Snake venoms in therapy

Snakes and their venoms have been regarded as of great medicinal value in India. Snake venom is called 'sarap visha' in Hindi and 'garala' in Sanskrit. The use of snake venom in Hindu medicine is of comparatively recent origin, as references to it are only met with in such modern works as Ratnavali, Sarkaumudi, etc. The Hindu practitioners obtain the poison by making the reptile bite a piece of wood, and the poison flowing out is collected on a plantain leaf. It is preserved by drying or by rubbing with a little mustard oil and spreading it on the leaf. Although the venoms of other snakes are mentioned, it is chiefly the venom of the Indian cobra which is used.

Almost all the parts of the body of a snake have been used in one or other incurable disease. Dutt (1932) has given a long list of animal products which have been used in Hindu medicine, e.g., extracts of frogs, minced meat of lizards, skull bones of man, meat of sparrows, fats of bear and lion, feathers of the peacock, etc., have been used in different diseases. The use of cobra venom has also been advocated in the treatment of leprosy, incurable ulcers, bleeding, etc.

Ainslie (1826) wrote that the flesh as well as the skin of certain snakes was believed to possess medicinal properties in some of the Eastern countries. In *Ulfaz Udwiyeah* the flesh of snakes is described as possessing 'hot' and 'dry' effects. The dried and powdered flesh of 'Tamool' (an inoffensive hill snake),

and the Malay 'Paumboo', has been known as a remedy against leprosy. The moults of snakes powdered and mixed with oil of *Dalbergia arborea*, when applied externally, is considered of value in epilepsy. The blood has also been used in Mohammedan medicine in the treatment of leucoderma. A preparation of arsenic and dead cobra is applied externally to leucoderma patches and syphilitic rashes in northern India. The wild tribes of North Burma and Shan States eat the flesh of certain snakes. The venom has also been used, in India as a drug of addiction, in the form of a pill. It is mixed with arsenic, opium and musk and is used as a tonic, aphrodisiac and a prophylactic against many diseases. It has been used as a hepatic stimulant in ascites, cholera, collapse, etc.

its efficacy in epilepsy has been revived. Its use in therapeutics is based on its depressing properties on the nerve cells.

It is said that the pathological effects of any given venom on man vary with the dose injected. While large doses are lethal, small doses produce beneficial physiological effects.

The rationale of application of venom in therapy.—The application of venom in medicine may be based on the presence of the following active principles: (a) neurotoxin, (b) cytolytic (with absorption of granulation tissues), (c) coagulative and hæmorrhagic enzymes (production of protein and histamine-like shock) and (d) protective properties against rabies and epilepsy (see table III).

TABLE III

Therapeutic indications of active principles of snake venom

Active principle	Venom	Action and uses
Neurotoxin	Cobra	Depressant to psychical and medullary centres. Heart stimulant. Paralysis of nerve and plates. Sedative in delirium, hysteria, epilepsy, painful cancer, metastases, meningitis, asthma, and low blood pressure.
Hæmorrhagin	(i) Viper	Fall of blood pressure, intravascular clotting and hæmorrhages.
Agglutinin	(ii) Crotalus	Hyperpiæsis, menorrhagia, hæmophilia, purpura and epistaxis.
Thrombase	Cobra	Bleeding piles.
Protein desensitizer	Do.	Epilepsy, asthma, erysipelas and carbuncles (allergies).
Immunizer	Crotalus	Rheumatism and rabies.
	Bee venom	Epilepsy.
	Crotalus	

Snake venom, particularly the venom of *Naia naia* and *Lachesis trionocephalus*, has been used in homœopathic medicine for the last 50 years. The venom next in importance is that of *Crotalus horridus*. Muir in South America used the venom of *Crotalus casavella*. Other venoms used are that of *Bothrops lanceolatus*, *Elaps*, *Apis mellifica* and *Arachnids*. The majority of diseases in which the venom of lachesis is indicated in this system are abscesses, carbuncles, erysipelas, cancer, apoplexy, paralysis, meningitis, mental diseases, asthma, tuberculosis, syphilis, chorea, flushes, metrorrhagia, hæmophilia, hæmoptysis, skin diseases, and the diseases of the teeth. Cobra venom is indicated in diphtheria and malignant tumours.

In Western medicine rattlesnake venom (crotaline) has been used in a number of diseases. It is said to have been employed beneficially in the treatment of pulmonary tuberculosis, acute pneumonia, pulmonary gangrene, asthma, chronic spasmodic cough, hoarseness, neuralgia, chorea, epilepsy, hysteroepilepsy and hæmophilia. The use of the venom for respiratory and nervous affections has been discredited, but quite recently interest regarding

Neurotoxin.—The neurotoxin principle is present in all snake venoms though it preponderates in cobra venom as compared to the venom of vipers and other snakes. This principle has a strong depressant action on the higher centres. Its action is particularly marked on the vasomotor and the respiratory centres. In small doses it has an irritant action, but in large doses or on prolonged contact it produces paralysis of both the sensory and motor end-plates. The venom, therefore, in graduated doses may be used to depress the higher psychical centres and is useful in delirium, hallucination, aphasia and melancholia. Improvement may occur in apoplexy, meningitis, hysteria and chorea. It may be used to depress the respiratory spasms of the asthmatic attack. In small doses it may be useful in early stages of hemiplegia and paraplegia. On account of its producing anaesthesia by paralyzing the sensory nerve endings it has been used locally to stop the severe pains of inoperable carcinoma.

Cytolytic and tissue absorption.—The venom produces necrosis by damaging the intima layer of the blood vessels when it is injected intravenously. Recently it has been experimentally

of the finer blood vessels and consequently gives rise to ecchymosis and extravasation of blood, and the convulsions seen early in viperine poisoning are due to small hæmorrhages in the cerebral cortex, a cytolyisin which dissolves the red blood corpuscles and a fibrin ferment (thrombase) causing intravascular clotting, pulmonary embolism and death from asphyxia. The slow and delayed symptoms after injection of the venom are due to its remaining localized. The fatal dose for a monkey of 25 kilogrammes weight is 7.5 mgm. and for man the M. L. D. is 42 mgm., death occurring in 24 hours. The average dose given at a single bite is about 72 mgm., which is more than double the minimal lethal dose. Crimmens (1931) stated that the diamond back rattlesnake of Texas may discharge 9 to 40 lethal doses of the venom at one bite. In the case of the echiis the M. L. D. for a monkey is 0.5 mgm. and for a man is 5.0 mgm. and the approximate dose of the venom injected at a single bite is about 12.3 mgm. (Acton and Knowles, 1914). Here also the snake injects almost double the fatal dose. Chopra and Chowhan (1934) investigated the pharmacological action of the venom of Russell's viper, and found that the hæmorrhagic phenomena appear at the outset of poisoning and are very extensive in character. Death is preceded by spasmodic and irregular respiration, convulsions and asphyxia indicating the involvement of the vagal centre owing to deficient blood supply. In all post-mortem examinations recorded, the lungs show symptoms of asphyxia, petechial hæmorrhages and infarctions. The right side of the heart is full of dark blood and the left side is empty and tonically contracted. In frogs the venom produces less harmful effects. In animals which have died of daboia poison the kidneys show inflammation, mottling of the cortex and extensive hæmorrhages. The serous cavities such as the pericardium, the pleura and the peritoneum are full of sanguineous fluid, probably produced by injury to the delicate endothelial cells of the capillaries, leading to excessive leakage of the blood.

The daboia venom has a marked tendency to produce thrombosis and gangrene at the site of the bite and death is due to secondary shock. The systemic blood vessels, especially the peripheral ones, are found to be contracted and those of the splanchnic area are widely dilated, as in histamine shock. That the nervous centres are not much affected is shown by the fact that in decerebrated animals exactly the same results are produced. If the action is prolonged, these measures are of no avail since the normal relative permeability of the vessel walls to the protein constituents of the blood is lost. Capillary leakage goes on to such an extent that anything injected leaks out of the vessels. The symptoms of shock in daboia poisoning are not due to reflex impulses, but to the local dilatation of the capillaries of the

splanchnic area. The paralytic action of the venom seems to be confined to the capillaries only and is similar to histamine.

In the case of lachesis, Vellard and Vianna (1932) found that intramuscular and subcutaneous injections in dogs produce an initial incoagulability by rapid destruction of fibrinogen and of the complement by the protease of the venom; subsequently there is absence of formation of thrombin due to the action of the venom on the hepatic cells and hæmolysins are also increased. After intravenous injection there is at first intravenous clotting, followed by incoagulability of the blood in about five minutes. It was further shown that, while the venoms of lachesis and trimeresus are anti-complementary, cobra venom has less and slower anti-complementary action and crotalus has no action on the complement at all. A certain incubation period precedes the anti-complementary action. Malcolm Smith and Hindle found that the M. L. D. (for mice) of the venom of the pit viper (*Trimeresus sumatranus*) and *T. vagleri* to be 0.5 mgm. and 2.45 mgm. per kilo. body weight, and that of the sea snake (*Latecauda colubrina*) to be 0.113 mgm. but they doubt that the total yield of the venom for any of these three species is sufficient to render the bite dangerous to a healthy adult person.

Snake venoms in therapy

Snakes and their venoms have been regarded as of great medicinal value in India. Snake venom is called 'sarap visha' in Hindi and 'garala' in Sanskrit. The use of snake venom in Hindu medicine is of comparatively recent origin, as references to it are only met with in such modern works as Ratnavali, Sarkaumudi, etc. The Hindu practitioners obtain the poison by making the reptile bite a piece of wood, and the poison flowing out is collected on a plantain leaf. It is preserved by drying or by rubbing with a little mustard oil and spreading it on the leaf. Although the venoms of other snakes are mentioned, it is chiefly the venom of the Indian cobra which is used.

Almost all the parts of the body of a snake have been used in one or other incurable disease. Dutt (1932) has given a long list of animal products which have been used in Hindu medicine, e.g., extracts of frogs, minced meat of lizards, skull bones of man, meat of sparrows, fats of bear and lion, feathers of the peacock, etc., have been used in different diseases. The use of cobra venom has also been advocated in the treatment of leprosy, incurable ulcers, bleeding, etc.

Ainslie (1826) wrote that the flesh as well as the skin of certain snakes was believed to possess medicinal properties in some of the Eastern countries. In *Ulfez Udwiyeah* the flesh of snakes is described as possessing 'hot' and 'dry' effects. The dried and powdered flesh of 'Tamool' (an inoffensive hill snake),

used in South Africa. It is believed that alternate hypodermic and intramuscular injections of venene are useful in hysteria and other nervous conditions such as neurasthenia, illusions, nervous exhaustion, asthenia, profuse and painful menstruation, chorea and paralysis. It has a lasting tonic effect on the cardiac muscles. It is said to accelerate metabolism, soften the walls of the blood vessels and restore the circulation and nutritional processes to normal. It is believed to arrest premature senile decay. Venene treatment, however, still requires further investigation to establish its claims in therapy.

Mackenzie Wallis, W. D. Nicol, N. Craig and others have suggested the presence of an allergic element in a certain proportion of cases of epilepsy and the benefit such as resulted from venom treatment may well have been due to desensitization produced by its injections. In the treatment of epilepsy the venom is given in doses of 1/200 gr. by hypodermic injection; 3 to 5 injections being given at 8-day intervals; afterwards two more doses of 1/75 gr. are given at 14-day intervals. If the symptoms do not disappear, another dose of 1/25 gr. is recommended. It has been advised that during treatment the administration of bromides should be discontinued. The dose and the interval of administration are to be varied according to the age of the patient and the nature of the injury. Fitzsimons pointed out that this method of treatment is not free from danger unless the venom is properly prepared by skilled hands.

Asthma.—Spangler (1925) used intramuscular injections of the proteins of the venom of the rattlesnake (crotonine), which contains a peptone and a globulin, for non-specific desensitization therapy in allergic asthma. An increase in the percentage of eosinophil cells, lengthening of the clotting time of the blood, increasing the permeability of the vessel walls and production of general cell and granular stimulation are all recognized factors in the mechanism of non-specific protein reaction. He took the degree of eosinophilia produced as a guide to dosage and frequency of administration of the proteins. Usually the highest rise in the percentage of eosinophiles following venom protein injection, in doses of 1/400 to 1/50 gr., occurs by the second or third day. Within 5 to 7 days the eosinophiles will usually have dropped to 4 per cent or less, and then the patient may be given another injection. The strength of the dose is not increased if a given strength produces an increase of 8 to 10 per cent of eosinophiles by the second or third day after an injection. By continuing the injections the rise of eosinophiles gradually becomes less and finally does not exceed the normal limits. The patient is then non-specifically desensitized.

Uterine hæmorrhages.—Peck and Goldberger (1933) treated patients suffering from functional bleeding. The venom of *Ancistrodon piscivorus* in solution of 1 in 3,000 in normal saline

was used and 1 in 10,000 merthiolate was added. It is given intradermally in doses of 0.2 c.cm. and subsequent doses of 0.4 c.cm. bi-weekly; improvement occurred within 5 days to 2 to 3 weeks. In some cases six injections were given during a period of 2 to 3 weeks with the control of bleeding; anæmia also improved considerably. The treatment should be continued for at least 3 months after the clinical improvement has manifested itself. During the first 5 to 6 injections care should be taken that the sites of injection are separated by at least 10 cm. The left arm and right thigh can be used alternately. If hypersensitivity occurs it is better to reduce the concentration of the solution to 1 in 10,000 and to continue the dose until 0.4 c.cm. of 1 in 3,000 is reached. The plan of injection to be followed is given below :—

1st injection	.. 0.1 c.cm. of 1 in 10,000
2nd "	.. 0.4 c.cm. of 1 in 10,000
3rd "	.. 0.2 c.cm. of 1 in 6,000
4th "	.. 0.3 c.cm. of 1 in 6,000
5th "	.. 0.1 c.cm. of 1 in 3,000
6th "	.. 0.4 c.cm. of 1 in 3,000

Antivenene also has been used by Stockton and Franklin (1931) in the cases of hæmorrhagic diseases. In severe cases of bleeding, where almost every kind of treatment has failed, the patient was desensitized by giving small intracutaneous injections of antivenene in doses of 0.1 to 0.2 c.cm. every half hour and when desensitization to anaphylaxis has occurred 10 c.cm. of antivenene were injected subcutaneously on the inner surface of the thigh. The bleeding is said to have stopped almost immediately.

Hæmophilia.—The coagulant action of different venoms has been suggested by various workers and has been experimented on in normal human blood and citrated plasma both *in vivo* and *in vitro*. The application of this coagulant property present in snake venoms and its use in hæmophilia was suggested by Prof. Hartridge. It has been noticed that neither coagulant nor anticoagulant action is common to any large zoological group of snakes. In allied genera the venoms of some quite nearly-related species are markedly opposite in action. The only large genus in which the venom is consistently coagulant is the viper. The Indian daboia venom (*Vipera russelli*) was found to be by far the most powerful coagulant agent against hæmorrhage. In the case of hæmophilia it was noticed that once the coagulation started with this venom the process of fibrin formation was completed rapidly. The clot produced was tough and elastic, in marked contradistinction to the soft slowly-forming ineffective clot characteristic of the hæmorrhagic diathesis. Experimentally one drop of Russell's viper venom in concentration of 1 in 1,000 when added to 10 drops of hæmophilic blood clotted it in 17 seconds, whereas the blood from the same patient clotted spontaneously in 35 minutes. In dilutions of 1 in 100,000 the coagulation time

indirectly responsible for the disintegration of the corpuscles, it will be observed that atebirin and plasmoehin did not precipitate the attack, whereas quinine succeeded in bringing it about on two occasions out of three. It would appear, therefore, that the hæmoglobinuria is not dependent on quinine alone, but some other factors also play a part in the production of this condition. What these factors are remains to be worked out. Many of the cases of black-water fever met with in Bengal and Assam are of this nature and it is possible that the substitution of atebirin for quinine in the treatment of malaria will bring about a reduction in the occurrences of such cases.

A CASE OF PAROXYSMAL TACHYCARDIA AND ITS SEQUEL

By G. T. BURKE, M.D., F.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Medicine

and

M. ABDUL HAMID, M.D. (Lucknow), M.R.C.P. (Lond.)
Reader in Pathology, King George's Medical College,
Lucknow University

The attack.—S. L., Hindu male, aged 23, was admitted to hospital on 7th March, 1934, with the complaint of continuous palpitation of four days' duration. He gave no history of any previous disease other than occasional fever; he denied venereal infection. He had been subjected to recent severe mental strain, as in the Bihar earthquake in January his house came down and all his family except himself were killed.

Severe and continuous palpitation started while he was in the train four days previously; the discomfort was increasing, but there was no pain, no œdema anywhere, and no subjective dyspnoea; the patient was very cyanosed.

The pulse was 180 per minute, perfectly regular, and of normal volume and tension. The cardiac impulse was diffuse, and the apex beat 1 inch outside the nipple line; there was a systolic thrill and the impulse was forcible; a soft systolic murmur was audible in the mitral and tricuspid areas, and the pulmonary second sound was accentuated. Beyond his colour, which was almost blue, and some basal pulmonary congestion, there were no other positive findings.

The Wassermann test was negative.

After a day's observation, during which he was on glucose and insulin, 5 units, the pulse remaining steady between 170 and 180, he was given intravenously one injection of strophanthin 1/125th grain, and the next day three of 1/100th grain with no effect. He was then put on 5 gr. doses of quinidine thrice daily, and after the sixth dose the pulse rate fell suddenly to 90, and remained at that rate thereafter. His colour became normal, and he left hospital relieved on 23rd March. The paroxysm had lasted for about ten days.

The sequel.—On 24th September, 1934, the patient was re-admitted for pain in the left back, fever, and dyspnoea, all of some 12 days' duration. He was found to have a left pleural effusion of clear fluid, some of which was removed and replaced by air on two occasions. Very shortly he developed a pericardial rub and then an effusion; this also was aspirated, and tubercle bacilli were demonstrated in it. There were no intra-pulmonary signs. The patient ran a continued fever of low degree, and became progressively worse until his death on the 7th December, 1934.

Post-mortem findings

Lungs: Right.—Slightly emphysematous. Right side of the pericardium was adherent to the lung on the right side. The adhesions were recent. The pleural cavity contained four ounces of fluid.

Left.—Covered with thickened pleura and collapsed at its base, where a sac had formed by the collection of some fluid in between the two layers of the thickened pleura. A chain of enlarged tuberculous glands was found in the left side of the neck. This chain had continued on to the anterior mediastinum, connecting up with the enlarged tracheo-bronchial chain of glands, which were found adherent to the pericardium and also to the left auricle whose walls were practically fixed to the posterior mediastinum, probably due to a previous adhesive mediastinitis, tuberculous in origin.

Heart.—The heart with its pericardial covering was very much enlarged—the greatest dimensions (after opening the pericardial sac and withdrawing the fluid) were 8 inches by 7 inches. The sac contained 8 ounces of dirty fluid, in which flakes of fibrin were seen floating. The inner side of the parietal pericardium was studded with tubercles, while it was adherent to the right lung with recent adhesions, but on the left side it had completely fused with the pleura. No adhesions of old standing were found in between the two layers of the pericardium. The visceral pericardium was covered with flakes of fibrin and was very rough. It could be compared to a 'bread and butter heart,' where butter was applied more profusely and irregularly. The heart as a whole was displaced to the right and at the same time slightly rotated to the left, so that the enlarged right ventricle had formed the apex, while the left ventricle was much smaller and formed the posterior surface of the heart. The left auricle was so adherent to the posterior mediastinum, that it could not be approached from outside. The mitral valve did not show any stenosis; the tricuspid admitted the tips of more than three fingers. The right auricle was enlarged. The blood vessels arising from the heart were covered with fibrin, but no actual strangulation by fibrous tissue was noticed around them.

Liver, spleen and kidneys.—Showed marked chronic venous congestion.

Morbid histology

Pericardium.—Showed uniform fibrosis with islets of small round cells here and there. Caseous foci were present at different places with some attempt at giant-cell formation.

Heart muscle.—Showed no fatty changes. Brown atrophy present in its early form.

Lymph gland.—Tuberculous.

Comments.—It is interesting that nine months before his death no signs of the infection from which he died were found in this patient. At that time it seemed probable that an emotional factor was the prime cause of the paroxysmal attack. This having ceased, there was no evidence of disease of the heart, a normal electrocardiogram being obtained. It is difficult to believe that, if a tuberculous focus had been the exciting cause, the normal rhythm would have been restored so easily.

Indian Medical Gazette

AUGUST

CEREBROSPINAL FEVER IN INDIA

MENINGOCOCCAL MENINGITIS, or cerebrospinal fever, as it is usually called, must be considered as one of the penalties of civilization. This claim is not dependent on the fact that the disease was not recognized clinically until 1805, when Vieusseux described an epidemic that had occurred in the south of France and in Switzerland, but on the history of the disease as we know it during the last century and a quarter. The disease occurs sporadically in most countries at any season of the year, but it is as an epidemic disease amongst confined communities that it attracts most attention, and it is man's gregarious tendencies that must be held responsible for its existence on the large scale on which it is to be found in many countries in both hemispheres at the present day.

Like other diseases that we associate with modern civilization, most notably tuberculosis, it seems to be taking a course contrary to that of civilization itself, and to be moving in an easterly direction. During the last few years the disease has been showing a very definite downward tendency in the United States, where some of the earliest and some of the most serious epidemics occurred, and in 1933 only about 3,000 cases were reported, whereas in recent years serious epidemics have been reported from Egypt and Turkey, and there has been a marked increase in the number of cases reported from eastern ports.

In India the disease was reported and accurately described as far back as 1878, and in 1883 an epidemic occurred amongst the convict labour force working on the Indus bridge at Sukkur; in this epidemic there were 38 cases and 27 deaths. From this time onwards occasional epidemics have occurred in jails and labour camps throughout the country. During the Great War a number of cases occurred amongst the Indian troops and in the labour forces, and at one time an isolation camp for carriers was established on an island in Bombay harbour. During the last few years there appears to have been a very definite increase in both the epidemic and the sporadic incidence of the disease and in 1934 the incidence curve rose sharply to nearly 3,000, from 458 in 1933. A typical institutional outbreak occurred at the Borstal Institution at Lahore in 1932. We have published two reports of this outbreak; in the first (Vol. LXVIII, p. 265) emphasis was laid on the clinical and in the second (Vol. LXX, p. 252) on the epidemiological aspects. There were 27 cases in a period of about 19 months,

but 16 of these occurred within the first six weeks of the epidemic.

In the present number will be found a report on another typical outbreak that occurred in an Indian training battalion at Nasirabad.

In Calcutta during the last two years there has been a steady incidence of this disease throughout the year; in one hospital, the only hospital into which these cases are systematically admitted, the admission rate averaged 50 cases per month (Vol. LXIX, p. 621) during thirteen months in 1933-1934, and only during the last few months has this sub-epidemic shown signs of abating. A similar state of affairs exists in many other towns in India, and the outlook is not unnaturally a source of considerable anxiety to those responsible for the health of the community, as this widespread incidence amongst the general population is a new feature in India.

Cerebrospinal fever holds a peculiar position amongst the acute infectious diseases in that it is probably spread almost entirely by healthy carriers and that only a small proportion of the human race appear to be susceptible to morbid invasion by the causative organism, though a much greater percentage are able to harbour it as a harmless commensal.

Under non-epidemic conditions when the carrier rate amongst the general population is low and each individual comes into contact with the minimum quantity of the specific virus, or does not come in contact with it at all, only the highly susceptible are picked out, usually children, but under epidemic conditions, when the carrier rate in a community rises to 20 per cent or even higher, each individual suffers a veritable bombardment, and if other factors, such as fatigue, sub-optimal nourishment and other infections, help to lower his resistance his chances of becoming infected are considerably increased, though even in these circumstances the case rate is never very high. Though the carrier state does not appear to confer any immunity, nevertheless the incidence of meningitis is usually lower amongst discovered carriers than amongst the rest of the community, presumably because in the highly susceptible a meningeal infection follows the nasopharyngeal infection so rapidly that there is no time for them to be discovered as carriers.

We have referred to the Borstal outbreak as a typical one; there was little evidence of a steady extension from one section of the institution to another, but within a few weeks the infection had spread throughout the institution and a case or so had occurred in nearly every section. After this the progress of the epidemic slowed down, there were 10 cases in the next ten months, and then finally an isolated case 19 months after the commencement of the epidemic. The carrier rate of the institution was found to be 12.83 per cent and the highest case rates were associated with the highest carrier rates. The population of the institution

is about 1,700 but it is not a static one, so that the incidence was not more than 1 per cent of those that came in contact with the infection. The incidence is typical because of the extremely rapid dissemination of the infection throughout the institution and because the final case rate was less than one per cent of the total population at risk.

The Nasirabad outbreak also has many characteristic features. The population was again an ideal one, consisting mainly of young adults, who were in addition subjected to unaccustomed fatigue. The permanent staff of the depot, amongst whom were a high percentage of carriers, suffered little, but the cases occurred amongst the new recruits. The cessation of the latter outbreak was probably due to the energetic measures that were taken, but epidemics of cerebrospinal fever have a habit of ceasing suddenly, though admittedly they are less likely to do so when the fire is being intermittently fed with fresh fuel.

The rapidity with which the infection spreads makes it difficult to check it in a closed community, when it is once established, even by the detection and segregation of carriers, and this measure is quite useless if they are sought amongst contacts only; a safer method is to isolate the whole community and to adopt methods of general hygiene within it. When one has to deal with a large population, such as that of a town, the isolation of carriers is out of the question, and it seems doubtful if much can be effected by the closing of schools, and places of entertainment. One is driven to seek consolation in the provision of efficient treatment.

The introduction of the serum treatment of cerebrospinal fever has brought about a very considerable improvement in the prognosis. The death rate was at one time seldom below

75 per cent, but nowadays reliable statistics showing a death rate of 33 per cent are quite common. However, even when anti-serum is employed a much higher death rate sometimes results, as high as 80 per cent in some instances.

In the two institutional outbreaks referred to above the death rates were 55 and 41 per cent, respectively. The standard commercial anti-serum is prepared from meningococcal strain 'types' I and III. A certain amount of 'typing' of the local strains has been carried out, both in Calcutta and at Kasauli, and from the results so far obtained, it seems that the large majority belong to one or other of these 'types'. The commercial anti-serum should therefore be effective, but it is quite possible that there are local sub-types against which a true autogenous serum would be more effective.

It is therefore of great importance that as large a number as possible of strains of meningococcus should be collected in different parts of the country and separated into their various types and sub-types. It may be found that strains collected in Calcutta differ from those collected in Lahore to the extent that they agglutinate at a slightly higher titre with their autogenous serum than with the apparently homologous serum prepared from strains collected in the latter town. If this is the case, it will be necessary to prepare serum for each province or even for each town as it has been repeatedly shown that serum made from locally-isolated strains is the most efficacious. In any case it is almost certain that a more effective anti-serum than is at present available can be prepared if a large number of Indian strains are collected and pooled. This has already been done in at least one town in India, but it is probable that a still more efficacious serum might be produced if more strains were used in its preparation.

THE QUESTION OF MARRIAGE IN PULMONARY TUBERCULOSIS*

(A CRITICAL CONSIDERATION WITH SPECIAL REFERENCE TO INDIAN CONDITIONS)

By Y. G. SHRIKHANDE, B.Sc., M.B., B.S., T.D.D. (Wales)
King Edward VII Sanatorium, Bhowali, U. P.

THE advice of medical men is often sought by tuberculous patients and their guardians on the question of marriage and married life. Two questions are generally asked—Whether a tuberculous patient should enter the married state? and—If the patient is already married, should the non-consumptive partner continue to live with the consumptive patient?

As the future happiness of the patients depends on the advice they receive, it is natural that they should expect correct guidance from their physicians. In view of the fact that tuberculosis is becoming very common in this country, especially among young people of marriageable age, it will not be out of place to consider these questions in some detail.

These questions involve a consideration of the following factors:—

- (1) Whether there is any danger of transmission of the disease to the healthy partner.
- (2) Whether there is any danger to the children born of consumptive parents.
- (3) Whether married life affects adversely the health of the patient.

* Being a paper read at the King George Thanksgiving (Anti-tuberculosis) Fund Conference held in New Delhi on 11th Dec. 1934.

Effect on the healthy partner.—It has been a very common experience that pulmonary tuberculosis in both husband and wife is rare in spite of the fact that they come into more intimate contact with each other than anybody else. Even in families where most of the children have been affected with tuberculosis, it has been found to be rare for both mother and father to be suffering from the disease.

A great deal of statistical work has been done in this connection. Mongour found that among 440 married couples in whom one of the consorts was suffering with tuberculosis, in only 4 per cent was the partner also found to be suffering. Thom found only 3 per cent in 402 couples. Levy found 2.8 per cent in 317 couples who were living in poverty and sharing the same bed.

A very interesting case is that of Metchnikoff who, despite the fact that for four years he remained in close association with his wife suffering from advanced tuberculous disease and took no precautions against contagion, he remained free from the disease for 44 years from the time of his marriage.

Ward, on the other hand, found that over 50 per cent suffered from conjugal tuberculosis in the working and lower middle classes and he tried to prove that direct infection played an important part in the spread of the disease. But Ward did not take into consideration the associated conditions, such as overcrowding and general insanitation, that could be held responsible for producing a higher percentage of incidence among the consorts of the patients.

Longstaff, basing his results on mathematical calculations which he deduced from the Registrar-General's reports, came to the conclusion that the prevalence of marital tuberculosis was not greater than might be expected as a matter of coincidence. He says, 'If the results are anywhere near the truth, they show that a far greater number of coincidences of the death of both husband and wife from phthisis, within a short period of one another, would be required to prove that one had contracted the disease from the other by infection'.

The above facts show clearly that the danger of transmission of the disease to the consort is not very great. The reason for this is not very difficult to find. The unaffected partner has, in all probability, been infected in childhood and reinfection is unlikely. Experimental work has shown that a very large majority of people in civilized countries become infected with the tubercle bacillus within the first few years of life and immunity is developed in them which is sufficient to protect them in future life from all ordinary exposures. Married people are no exception to this rule. Whether the consort will develop the disease depends on factors other than mere association with the consumptive partner.

It cannot, however, be denied that in the spread of the disease opportunities for acquiring infection from those who are the source of dissemination of the bacilli must play an important part. At the same time, it must not be ignored that the important factor determining whether a person will develop the disease or not is the power of resistance possessed by the individual. In other words, the seed comes to all, but whether it will germinate or not is determined by the soil on which it settles down. As mentioned above, the tissues of the body of the consort no longer remain vulnerable, but become highly resistant to further attacks of the bacillus on account of the protective reaction which they develop in the shape of immunity as a result of the infection which the consort had received in childhood.

The disease if and when it occurs in the consort may be accounted for by environmental conditions, such as overcrowding, general insanitation, poverty and diminished resistance, which last condition may be brought about, in this country particularly, by tropical diseases such as malaria, kala-azar and dysentery, as well as by the peculiar social customs and prejudices of the people.

Take, for instance, the purdah system and child-marriage which, as a rule, go together. There can be no doubt that purdah is one of the most important social customs that helps in the causation of tuberculosis in India. By shutting out sun and fresh air, it helps to develop the disease in women. Similarly with child-marriage, these young girls while yet incompletely mature are subjected to the physical strain of pregnancy, confinement and parturition. Is it difficult to conceive that under these circumstances tuberculosis in female consorts should occur in greater frequency? Why blame the tubercle bacillus for causing the disease when the ground has been made ready for it by these obnoxious customs? Our thanks are due to Dewan Bahadur Harbilas Sarda for bringing about the much-needed reform although experience has so far shown that the Sarda Act has not achieved all that its originator hoped of it.

Carl Pearson and Pope from an investigation of 40,000 married couples came to the conclusion that there is an excess of tuberculous infection between husband and wife beyond what chance alone would account for and they believed that this excess might be due, in part at least, to what they called 'assortive mating'. This slightly increased frequency of infection which might exist amongst the middle and professional classes, in whom assortive mating is possible, is probably due to the fact that persons with a tendency to tuberculosis possess certain common mental and physical traits which excite sexual attraction between them and lead to unconscious mating of like with like.

The factor of assortive mating does not, however, enter into consideration on the question of marriage in this country and even in western countries assortive mating does not exist to any appreciable extent in the poor classes. Therefore the increased frequency of tuberculosis in married people must be accounted for by the intensity of environmental infection from overcrowding, general insanitation and diminished resistance brought about by adverse conditions of life.

There is, however, one point which must be taken into consideration with reference to Indian conditions. The possibility of increased marital infection may be accounted for by the presence of what is called 'virgin soil' in this country, due to the fact that infection with the tubercle bacillus has not penetrated every place. It is possible for this reason for a phthisical patient to give infection to his or her uninfected healthy consort who might have come from virgin soil. With the growth of urbanization and industrialization, however, that is now taking place, the factor of virgin soil will soon disappear and infection to the healthy consort after marriage will become negligible as is the case in western countries.

Danger to the potential offspring.—There can be no doubt that the danger of infection to the children of consumptive parents is very great. The probability of the child of a tuberculous parent becoming tuberculous is far greater than the probability of wife or husband being similarly attacked. No child is born with tuberculous infection. Tuberculin tests applied to children have proved beyond doubt that children are born free of tuberculosis. It is only after birth that infection is acquired. Since they are born free from tuberculous infection, they have no immunity developed in them. If, therefore, the new-born child remains in close proximity to the consumptive parent, it will become infected during infancy and succumb from a generalized form of tuberculosis. Patients with open tuberculosis should therefore not bear children, and if children are born under such circumstances they must be removed at once from the dangerous environment of the patient. If they are removed at once, there is no reason why they should not be as free from the danger of infection as any other children. Bang has proved this fact by means of experiments done in Denmark on calves born of tuberculous cattle; none of the calves that were separated immediately developed tuberculosis. The Grancher system of prophylaxis is based on the same principle as Bang's experiments. According to this system children are removed, while still healthy and uninfected, from their infected homes and sent to live with healthy families. This system was introduced in France in 1903 by Professor Grancher.

Whenever the Grancher system is not possible trial may be given to Calmette's B. C. G.

vaccine for the prophylactic immunization of infants. This vaccine is given to infants by mouth, as advocated by Calmette himself, within the first ten days of life. Calmette claimed very satisfactory results from this method of immunization.

It is especially dangerous for actively consumptive women to raise infants who will surely catch the infection from her and die. The danger of infection to the infant is not from mother's milk, as is popularly believed, but from intimate contact with her, which brings about massive infection from her sputum. As we know, suckling children from the mother's breast is a very common practice in India. Infants in India therefore run a very great risk of infection as compared to infants in western countries where this practice is not so universal. Moreover, the economic condition of the people in this country is such that it is not easy to separate the child from the mother. A very practical method under these circumstances would appear to be to stop the production of sputum in the mother by the use of artificial pneumothorax or other collapse-therapeutic measures. The mother is thereby not only made a harmless member of the family, but she also regains the right of motherhood and can bear healthy children and bring them up herself.

It might be asked whether a child born of tuberculous parents is more liable to tuberculosis than a child of non-tuberculous parentage. It has not been proved definitely that there is anything specific in the inheritance from the tuberculous parent that makes the soil more susceptible to tuberculosis than a child born from parents who are suffering from reduced vitality from any other cause. All things being equal, the stronger and healthier the parents the stronger and more resistant the child. If the child of tuberculous parents does suffer from tuberculosis, it is more probably due to the unhealthy environment under which the parents live than to the presence of the bacillus itself. In fact, it is believed by some that the children born of tuberculous stock withstand the disease better because they have greater immunogenic power developed in them than those of non-tuberculous families.

Effect of the married state on the patient.—The effect of the married state on the patient is necessarily somewhat different on men and on women. On the average male patient, sexual intercourse has the same effect as on an average person who is not in good health. Excessive intercourse will affect his health for the worse just as it will affect any man's health who is feeling below par. Complete abstinence is undoubtedly the ideal course to adopt but since this is not practical in the case of every patient moderation is the safest course that one can advise. If moderately indulged in, sexual intercourse is not likely to do much harm; it may

even be desirable because it would prevent unnecessary brooding over enforced abstinence; which must prove harmful in the long run. Moreover, the married state might preclude venereal complications which would affect adversely the course of the tuberculous infection.

It is a popular belief, also shared by the medical profession, that tuberculous patients suffer from increased sexual irritability and it is a remarkable fact that even in the advanced stages of the disease sexual potency may be retained. This sexual irritability has been attributed to the toxæmia caused by tuberculosis and also to the indolent life that the patient has to live, under treatment. Under these circumstances, complete abstinence would seem to be a counsel of perfection. The duty of the medical men should be to tell the patients about the bad effects that may accrue from over-indulgence and advise them to observe the golden rule of moderation.

With women things are somewhat different. So long as they do not become pregnant there seems no reason why they should not enjoy their married life in moderation. As a matter of fact, the married patient is often better situated than the single because there is a partner in life to look after him or her. Very often it has been found that a good woman has helped her consumptive husband towards recovery, which would have been difficult if the patient had remained unmarried. Similarly, many a female patient has recovered after marriage to a man who gave her a good home, proper care and nourishing food. In short, the financial resources affect the question of marriage considerably, as they provide the patient with the means of carrying out the necessary treatment.

The effects of pregnancy on consumptive women have not been properly appreciated and divergent views have been expressed on the point. One school believes that pregnancy often ameliorates the condition of female patients and, therefore, on this assumption recommends marriage for tuberculous girls. In India, it is not uncommon for *hakims* and *kavirajis* to recommend marriage for girls who are suffering from tuberculous disease. The reason for this recommendation may perhaps be that married life stimulates the endocrine system of the patient and endows her with a certain degree of immunity.

There is no doubt that during pregnancy the patient very often looks better and the disease appears to abate. The explanation for this may perhaps be found in the circulatory changes that take place in the patient during pregnancy. The mucous membranes of the respiratory organs are congested and this probably retards the progress of the disease for the time being, just as is the case in mitral stenosis. It is also very probable that in pregnancy the enlarged

uterus pushes up the diaphragm and keeps the lung compressed as occurs following phrenic evulsion. After confinement, the diaphragm descends, the upward pressure is removed from the lung, and the disease begins to advance again. It may be possible to prevent this sudden decompression of the affected lung by the application of a tight bandage beneath the breasts whereby relative compression and immobilization of the lung is obtained. It would be interesting to find out if phrenicectomy done immediately after confinement would keep the disease in check.

The second school holds that pregnancy, labour and lactation are liable to reactivate latent tuberculosis and cause aggravation of active lesions. More recent statistics, however, do not bear out this contention. The rational view on this question would appear to be that, while pregnancy in women with active and progressive lesions is fraught with danger because the disease in such cases is very liable to advance rather rapidly after child-birth, in chronic, quiescent and arrested cases no harm ordinarily results from it.

It is not so much the single pregnancy as multiple pregnancies at short intervals that prove injurious. Repeated pregnancies must therefore be avoided especially when active lesions are present in the lungs and preferably for some time, say two or three years, after all symptoms have subsided.

Consumptive women should be given instructions on the use of contraceptives, when celibacy is not possible. If they still become pregnant conservative treatment should be tried first of all. When this fails, then only should therapeutic abortion be considered. Experience has, however, shown that, while abortion is not required in quiescent cases, in active and progressive ones it rarely saves the patient's life.

The demand made by certain people that tuberculous patients should not be allowed to marry is devoid of all common sense and not practical at all. The remedy will be found to be worse than the disease itself. The race is not in danger of deterioration because of children derived from tuberculous stock. It has been shown above that tuberculous cattle have been used for breeding purposes by removing the calves immediately after birth. The same may hold true in the case of human beings. And what remedy would be applied against those who were already married before the advent of the disease? Moreover, prohibition of legal marriage does not exclude extra-marital sexual intercourse. Free instruction on the prevention of conception is likely to be of greater value than the prohibition of marriage.

It must be remembered that the tuberculous patient has the same desire for home and love as anybody else and in giving advice we must be 'practical' though this may fall short of the 'ideal'.

Conclusion

The problem of marriage in tuberculous patients and tuberculosis in married patients is bound up more with social and economic considerations than the mere question of infection from one party to the other. Provided that the usual common-sense precautions are observed, there appears to be no more risk to the consorts of tuberculous patients than to anybody else in frequent contact with the patient. Nor is there so much danger, as is popularly believed, to the

patient from married life provided it is not lived recklessly. Tuberculous patients who contemplate marriage should wait for some time after all symptoms of active mischief in the lungs have ceased. In females, conception should, as far as possible, be avoided at least as long as active lesions are present in the lungs. The danger of infection to the children can be avoided by separating them from their parents immediately after birth (Grancher system), or minimized by the use of B. C. G. (Calmette method).

DIPLOMA IN GYNÆCOLOGY AND OBSTETRICS

THE Government of Madras have recently instituted a diploma in gynæcology and obstetrics. This diploma will be styled L.G.O. (Licentiate in Gynæcology and Obstetrics) and will be awarded to candidates who undergo a special course of clinical training at the Government Hospital for Women and Children, Madras, attend the prescribed tutorial classes and pass the final qualifying examination at the end of the course. The course is open only to non-graduate medical men and women of not less than five years' standing. The number of candidates to be trained at one course will not exceed six. The following fees will be levied from all candidates other than those in permanent Government service under the Madras Government: (a) the fees for the course is Rs. 100 for the first quarter and (b) Rs. 50 for every subsequent quarter; (c) examination fee Rs. 30. Full details of the scheme can be obtained from the Superintendent, Government Hospital for Women and Children, Egmore, Madras. Applications for admission to the course should be made to the Superintendent of the above hospital.

BENGAL MEDICAL COUNCIL

EXTRACTS from the Minutes of the Bengal Council of Medical Registration, held on the 13th August, 1934:—

1. The statement of minimum requisites to be satisfied by the Jackson Medical School, Jalpaiguri, for continuance of affiliation as drawn up by the committee appointed to inspect recognized medical schools was approved.

2. Government order accepting the proposal of the Council that under section 21 of the Bengal Medical Act, 1914, the title 'License in Tropical Medicine' granted by the Calcutta School of Tropical Medicine may be entered in the Register of Registered Practitioners as an additional qualification against the name of a registered medical practitioner was recorded.

3. Reports on the inspection of the under-mentioned institutions by a committee appointed by the Council were discussed and approved:—

- (a) Ronaldshay Medical School, Burdwan.
- (b) National Medical Institute, Calcutta.
- (c) Bankura Sammilani Medical School.

4. Report of the committee appointed by the Council to consider the rules for the provident fund of the office was approved.

5. Government notification announcing the appointments of the under-mentioned gentlemen as members of the Council were recorded:—

Dr. Subodhchandra Mitra, M.B., F.R.C.S., under section 4(f), Bengal Medical Act, 1914.

Major P. C. Banerjee, F.R.P. & S., I.M.S., under section 4(e), Bengal Medical Act, 1914.

Major S. Nag, M.R.C.P., F.R.C.S., D.T.M. & H., I.M.S., under section 4(e), Bengal Medical Act, 1914.

Major T. H. Thomas, M.D., M.R.C.P., I.M.S., under section 4(e), Bengal Medical Act, 1914.

6. The under-mentioned gentlemen were nominated representatives of the Council and the Governing Body of the State Medical Faculty of Bengal on the Bengal Sanitary Board:—

- (1) Dr. Taraknath Majumdar, L.M.S., D.P.H., D.T.M.
- (2) Dr. Abdul Majed, M.B., D.P.H., D.T.M.

7. It was decided that the under-mentioned schools be inspected during the next six months:—

- (1) Campbell Medical School, Calcutta.
- (2) Jackson Medical School, Jalpaiguri.
- (3) Chittagong Medical School.

8. The reports of the committee proposing amendments in (a) the Bengal Medical Act, 1914, and (b) the election rules under the Act were postponed for consideration at a special meeting before the next ordinary meeting.

9. A report of the Penal and Ethical Cases Committee was considered.

10. The Council decided to recommend to Government that the title F.S.M.F. (Bengal) granted by the State Medical Faculty of Bengal be recognized as an additional qualification registrable under section 21 of the Bengal Medical Act, 1914.

11. The proposal for revision of the Appendix to the Annual Medical List (Ethical suggestions, etc.) moved by Sir Kedarnath Das, Kt., C.I.E., M.D., F.C.O.G., was referred to the Penal and Ethical Cases Committee.

12. On an application from the Registrar, Andhra University, it was decided that a report be made to the local government under section 18 recommending that the M.B. B.S. degree of that University be recognized as registrable in Bengal.

13. Entry under section 21 of the Act of the qualifications D.T.M. (Liverpool) against the names of Dr. Mohinimohan Ghosh and Dr. Aminuddin Ahamad and D.T.M. & H. (London) against the name of Lieutenant-Colonel M. Das were approved.

14. With regard to the entry of the qualification D.B. (London U.) against the name of Dr. Ganapati Panja it was decided that an enquiry be made of the London University whether the diploma was one similar to that of D.O., D.O.M.S., etc., granted in the United Kingdom.

15. A statement of actual income and expenses of the Council during the year ending 31st March, 1934, was recorded.

16. The report on the audit of the accounts of the Council during the year 1933-34 was recorded.

17. The consideration of an application from Dr. R. Trey, M.D. (Cologne U.), for entry of his name under section 18 of the Act was postponed.

THE FORTY-FOURTH CHEMISTS' EXHIBITION, LONDON

THE forty-fourth exhibition will be held from 23rd to 27th September next in the new hall of The Royal Horticultural Society, Westminster, S.W. The management, 'The British and Colonial Pharmacist', is always pleased to welcome members of the drug trade from overseas and they are admitted on presentation of a business card. The exhibition—which in size and comprehensiveness is unequalled in the world—presents the latest products and attracts a very large attendance from chemists and druggists and all interested in the distribution of chemists' goods. Solely for the trade, it reflects the advance in the previous twelve months.

THE FIRST INTERNATIONAL BLOOD-TRANSFUSION CONGRESS, ROME

THE first international blood-transfusion congress will be held in Rome from the 26th to 29th September next.

For further information applications should be addressed to the 'Segreteria del 1° Congresso della Transfusione del Sangue, Via Palermo, 1, Milano, Italy'.

THE CALCUTTA DENTAL REVIEW

WE have just received the first issue of this new periodical.

The number of journals devoted to medical matters already appearing in India is very large but this one need have no fear of not being appreciated for it opens up an important field of medical science in this country, as it is to be devoted wholly to dentistry. In

recent years the influence of dental disease as the main aetiological factor in many general diseases has been much more widely appreciated, so that we as medical men have come to rely on the help of our dental colleagues in the cure of a large number of conditions. The natural effect of this is that the two professions (medical and dental), at one time looked on as more or less distinct from each other, are becoming much more closely allied in their efforts to cure and prevent human illness. As a consequence we welcome the publication of *The Calcutta Dental Review* both for itself and for the promise of help that it holds out to us as medical practitioners.

The journal is well produced and clearly printed and it contains a series of well-written and interesting articles. If the standard of the first number is maintained we predict an ever-increasing circulation for it and have much pleasure in welcoming this addition to our medical literature. The Calcutta dentists have previously given ample evidence of their energy and keenness in trying to improve the status of their profession, and we heartily congratulate them on this further evidence of their activity and wish their newest venture all success.

INDIAN MEDICAL COUNCIL

In pursuance of sub-section (2) of section 9 of the Indian Medical Council Act, 1933 (XXVII of 1933), the Governor-General in Council is pleased to appoint Lieutenant-Colonel G. T. Burke, M.D., B.S., F.R.C.P. (Lond.), I.M.S., to be the Secretary of the Medical Council of India, with effect from the 9th May, 1935. He is placed on foreign service under the Medical Council, with effect from the same date.

The Prevention of Disease in Infancy

By WILFRED PEARSON, D.S.O., M.C., M.A., M.D., F.R.C.P.
(From the *Journal of State Medicine*, Vol. XLIII, April 1935, p. 204)

DISEASES in infancy chiefly affect two systems, the digestive and the respiratory.

Throughout infancy the prevention of disease depends more upon feeding than upon any other factor, and no single preventive measure is of such importance as breast feeding. This is true in spite of the fact that the risks of artificial feeding have been diminished a good deal by the intelligent methods in use nowadays. Breast milk not only supplies all that is needful for the infant in the first eight months of life, but supplies it in a form which is most easily digested and utilized by the infant. It contains all the necessary salts and vitamins. If feeding is not possible for the eight months, six months will be a great advantage; but perhaps it is the first three or four months that matter most, and every effort should be made to feed the infant on the breast, if only for a limited time.

Nowadays iron and orange juice are sometimes advised as a routine for babies at the breast; these should not be necessary, and may upset the infant's digestion. If extras are to be given, it is to the nursing mother that they should be administered.

Cow's milk, modified to some extent, is the best substitute for the breast. Dried milks represent an advance in infant feeding; they are more digestible, keep well, and are free from infection. In all diets food should be given at regular intervals; the ingredients should be reasonably balanced as regards fat, sugar and protein; sufficient salts must be given in as natural a form as possible; and all the vitamins must be represented.

One of the chief faults in the past has been to use too high a proportion of fat; if this fault is continued with excess sugar (often provided in an unsuitable form) illness and inanition may result.

The commonest disorder of the alimentary system and one of the chief causes of infant mortality is diarrhoea. There has been a reduction of more than one-third in the mortality from this disease in the past 40 years; and factors in this improvement have been better education in the principles of infant feeding and cleanliness in the handling and distribution of milk.

It is by encouraging these safeguards that we may hope still further to reduce the incidence of diarrhoea, but valuable as they are none of them is such a safeguard as is breast feeding.

Scurvy is prevented by giving the infant orange juice to make up for any lack of vitamin C in the milk, whether dried or fresh. Nowadays scurvy is met with chiefly as a result of the use of milk which has already been pasteurized and is then boiled again in the home, of stale milk, and of certain kinds of 'infant food'. The amount of orange juice needed varies from three teaspoonfuls to six or eight; if the larger dose is needed it is best divided into three or four doses, as one large dose may cause indigestion.

When the infant has reached the age of nine or ten months and potato can form part of the diet much less orange juice is needed. Raw fruit and green vegetables are an advantage as laxatives and purveyors of valuable salts and should be given in addition to potatoes; but excess of them should be avoided, as they may cause indigestion.

Among the preventable diseases of infancy rickets was formerly one of the least often prevented. Though probably ill-balanced dietaries (especially excess of starch), lack of exercise, and impure air are contributory factors, the main cause of rickets is lack of

vitamin D in the diet. Rickets can therefore be prevented by providing foods, at first for the mother and later for the child, in which this vitamin is abundant, *viz.* milk, butter and eggs. It is safer to give to all artificially-fed infants some special preparation of this vitamin.

We know that sunlight acting on the skin creates a chemical substance similar to, if not identical with, vitamin D; natural and artificial sunlight are therefore adjuvants in the preventive treatment of rickets.

It is probably true to say that of all the vitamins, vitamin B is the least likely to be deficient, as it is present in so many different foods and is so little likely to be destroyed by any ordinary cooking process. Nevertheless at times it has to be specially provided as an extra for children who are not thriving or gaining weight.

Deficiency of salts must certainly be an important feature in producing ill-health and lack of resistance to infection, and it is important to provide the infant with some form of wholemeal flour, and to see that vegetables are properly cooked and that all the goodness of them is not, after cooking, thrown down the drain.

The supply of iron may fail after six months, particularly in the breast fed, and it may be necessary to give iron as medicine or in vegetables to counteract this tendency.

Prevention of dental caries should probably begin when the teeth are still forming in the jaws and are undergoing hardening or calcification. The better the tooth at the time of eruption, the better can it withstand decay. Attention should be given to the maternal diet, since teeth begin to calcify at the fifth month of uterine life.

There is little doubt that cleaning the teeth is important, as sticky foods tend to collect about the neck of the tooth and erode it externally. Food which encourages mastication and has a cleansing effect also is indicated theoretically, and it is often advised that the meal should end with raw apple, but common sense is needed in judging how far this is practicable, for often chronic indigestion is produced by giving food in this way.

We next come to infectious diseases, and since most infection enters through the mouth and nose, *i.e.*, is breathed, it is important to try to do all possible to stop the development of adenoids, tonsillitis, and unhealthy conditions of the nose, for the mucous lining represents the first line of defence against disease.

Active or interfering measures are not necessary; nasal breathing is to be encouraged and the use of dummies, for this reason, is taboo, and later on all children should be taught nasal breathing, breath holding, and proper breathing exercises to help to keep the nose, throat and lungs in a healthy condition.

The remaining efforts should be directed to conditioning the air indoors and to avoiding especially too moist or too dry a condition.

In damp and cold winter climates the strain put upon the linings of the nose and throat is severe, *e.g.*, as when coming out from a hot room into the cold, damp air.

I must also enter a plea, as much for your health's sake as for the infant's, to encourage the proper conditioning of air in public places and that steps be taken to attack this, one of the many problems which civilization and city life have created, *e.g.*, the fouling of the atmosphere with emanated heat and moisture of human beings crushed together with tobacco smoke and petrol exhaust fumes and fog.

This problem is of vital importance to the health, and I must mention again the importance of good food, adequate ventilation with moving air, and proper evacuation by bowel, skin and kidneys as general measures for keeping the child in good condition and able to overcome incidental infection, whether colds, pneumonia, or special forms of fever, such as measles.

Tuberculosis presents a special problem. There are two sources of infection, *viz.* (i) the inhalation of

infected sputum of an adult, and (ii) the drinking of infected milk, which is more common.

Prevention of infection by milk can be accomplished by boiling or pasteurizing, or T.T. milk can be used.

Children should also be shielded from adult infection, but this is one of those hopeless gaps in preventive medicine that need filling up. It should be a rule that no known actively tuberculous adult should be in a house where there are children. Since whooping-cough and measles are so often a predisposing cause, proper convalescence and tonic treatment are matters of importance.

Vaccination against smallpox is a preventive measure of indisputable value and should be adopted for every infant unless there is some special reason to the contrary. Sometimes it may be postponed until the child is two or three months of age, if he or she is frail, and there are feeding difficulties.

In conclusion it is necessary to mention that the needs of the brain and nervous system must not be overlooked. Sufficient sleep, careful and suitable feeding, plenty of fresh air, enough sunshine, and protection from excessive stimulation, whether due to noise or to light, are all called for. Other items of importance are proper attention to the skin, with bathing in warm or tepid water daily, and hygienic garments. Clothing should be loose, ventilated, soft and warm. Overclothing makes the body too hot and the skin unhealthy; it tends to weaken rather than to strengthen the child's resistance, though, of course, in the case of feeble twin infants sufficient warmth is most essential.

Finally, it may perhaps be useful to refer to two points which properly belong to the obstetrician, *viz.* twilight sleep and the diet of the expectant mother. Both, however, affect the health of the infant to a degree which brings them within the scope of this lecture.

With regard to twilight sleep there is sometimes a temporary feebleness of vitality in the newly-born state, sometimes sufficient to endanger life. Therefore the advisability of using this method as a routine may be regarded as open to question.

With regard to diet, no special diet is indicated for the expectant mother; she should take a well-balanced, normal diet, and if it contains sufficient milk, butter, green vegetables, fruit, eggs and potato, this will certainly provide all the beneficial ingredients necessary, salts and vitamins included.

In the last 40 years, curative measures have improved and have contributed to the saving of life, but the fall of infant mortality to nearly one-third of the figure at the beginning of this century has been largely accomplished by preventive measures. Continued dissemination of a knowledge of the elementary factors of infant hygiene should help still further to improve the standard of health in infancy and thereby lay the foundation for a healthier adolescence.

Ovarian Hormone Therapy

Review on an address delivered by Professor Aschheim at the meeting on 17th December, 1934, of the Medical Union of Luisestadt, Berlin

ALMOST simultaneously with the spreading of the knowledge regarding the cyclic changes of the uterine endometrium, the first research work concerning the female sexual hormones also commenced, after the internal secretory function of the ovaries had been ascertained by means of castration and transplantation of animal ovaries. The biological effect of the female sexual hormone and the method of standardizing were ascertained by experimental tests on rodents. Corner and Allen were the first to discover the existence of the second female sex hormone, the corpus luteum hormone, and that realizing it served the purpose of preparing for and maintaining pregnancy (gestation), they called it 'Progesterin'. Later on when purified hormone preparations were manufactured, these research workers succeeded in producing a true menstruation

in castrated female monkeys. The climax of experimental research, however, was reached when Kaufmann succeeded in proving that the effect of the two ovarian hormones 'Progynon' and 'Proluton' (progynon: follicular hormone, proluton: corpus luteum hormone) alone were sufficient to cause menstruation, as with the help of these two hormones he was successful in producing true menstruation in women, either castrated or suffering for years from amenorrhœa.

Only a few years ago ovarian deficiency was treated with extracts prepared from animal ovaries, without considering the fact, whether the animals were in a period of œstrus or not. The hormone contents of these organic ovary preparations, therefore, used to vary and were often practically nil. Nevertheless, in many cases of climacteric disturbances treated with such preparations there was remarkable therapeutic success. This is not very surprising as, since pure and standardized hormone preparations are produced, it is a well known fact that particularly during the climacteric age very small quantities of follicular hormone may suffice to do away with any disturbances. In severe cases, especially for nervous patients, a higher dosage from 5,000 up to about 50,000 international units daily (5 international units are equal to one mouse unit 'Sehering') should be administered either by mouth or by means of injections. The effects of high dosages of progynon B in oil are very remarkable. Serious menopausal troubles like vasomotor disturbances, unbearable headache as well as climacteric neuralgia of the pelvis and arthropathia can very often be obviated for a longer period by giving one or two injections of 50,000 international units of progynon B in oil. Skin diseases, particularly those found to be irresponsive to every other therapy like kraurosis vulvæ, pruritus vulvæ, vaginal ulcer of unspecific origin (observed by Kaufmann), acne rosacea, psoriasis and certain forms of eczema often respond excellently to progynon B in oil.

In cases of menstrual disturbances (amenorrhœa, oligomenorrhœa and dysmenorrhœa) Aschheim also recommends commencing treatment with peroral administration of small doses (progynon dragées). Only if this treatment proves unsuccessful should progynon B in oil be given. According to the lecturer's experience in cases of amenorrhœa it is possible to produce menstruation in every instance by a combined treatment of progynon B in oil (follicular hormone) and proluton (corpus luteum hormone), provided the uterus is not entirely undeveloped. Even in such cases of primary amenorrhœa, in which the uterus was considerably under-developed, the treatment was successfully applied. Occasionally Aschheim produced menstruation lasting for several days in uteri no larger than the size of a finger joint. So far the spontaneous menstrual cycle could not be achieved, but Aschheim considers it very important if, even for mere psychic reasons, artificial menstruation is produced in women suffering from primary amenorrhœa, as they very often acquire an inferiority complex which can be banished by the fact of menstruation taking place.

Secondary amenorrhœa responds more readily to this therapy and frequently spontaneous menstruations were observed following treatment with progynon dragées or progynon B in oil without proluton. As an explanation of the occurrence of spontaneous menstruations after progynon therapy, Aschheim points out that progynon also influences the anterior pituitary lobe.

According to Aschheim progynon has a decidedly favourable effect on the whole organism and increased intellectual efficiency as well as an improvement of the bodily and psychical condition of patients are repeatedly noticed after treatment with progynon. A full explanation for these facts has not been found as yet and it would be interesting if systematic research on the part of neuro-pathologists could be directed here.

The therapeutical application of proluton is rather limited compared with progynon. Aschheim mentioned that it is successfully used as a prophylactic against habitual abortion and in the treatment of

glandular-cystic hyperplasia (metropathia hæmorrhagica). It was expressly pointed out that, due to the fact that Butenandt succeeded in producing synthetic corpus luteum hormone, it is hoped that production on a large scale and at lower cost will be possible in the near future.

In regard to the therapy with gonadotropic hormones, Aschheim, who is one of the discoverers of these hormones, expressed rather sceptical views. He said it could not be denied that these hormones may do harm to the follicular system of the ovaries, unless it becomes possible to separate for practical application the two synergetically acting hormone parts of the anterior lobe, i.e., the hormone 'A' responsible for the ripening of the follicle and the hormone 'B' influencing the development of the corpus luteum. For many years Aschheim has, therefore, always used for treatment of ovarian dysfunction only the chemically pure and exactly standardized ovarian hormone preparations progynon, progynon B in oil and proluton.

Vaginal Ulcer—A Consequence of Ovarian Hormone Disturbance—Cured by Hormone Therapy

By DR. C. KAUFMANN

Report on an address read before the Society for Gynecology in Berlin on the 20th July, 1934

THE patient is 33 years of age. It is noteworthy that the first menstruation took place only when she was 33. This belated menstruation indicates ovarian deficiency. Once the menstrual cycle set in, it was regular for 4 years, when the woman became pregnant and gave birth to a healthy child. After delivery, menstruation soon set in again and was regular for 2 years. Afterwards the woman fell ill. Large ulcers appeared, at first on the left hand, later also on the upper thigh and the breast. These ulcers healed only very slowly leaving big scars. Simultaneously considerable brownish discharge occurred from the vagina. Large ulcers in the vagina were discovered. For several months attempts were made to heal the ulceration by means of washing and cauterization. This treatment was not successful. When the patient was brought to our clinic the posterior part of the vagina showed an ulcer about an inch in diameter with hard edges. The base of the ulcer was red and elevated. Spirochaetes were not found. The Wassermann reaction was negative. The histological examination of a specimen cut from the ulcer revealed that it was non-specific. We were unaware of the cause of this ulcer.

It was remarkable, however, that the ulceration occurred simultaneously with amenorrhœa. As the gynecological examination of the uterus and vagina proved these to be normal, the amenorrhœa could only be explained as being due to ovarian dysfunction. When discussing the therapeutic treatment to be adopted we started from the supposition that possibly the ulceration in the vagina was caused by ovarian hormone disturbances and consequently the patient was treated only with high doses of the benzoic ester of the dihydro-follicular hormone (progynon B oleosum), local treatment being completely abandoned.

In October 1933, the patient was given during 23 days in all 600,000 mouse units of the above form of follicular hormone, i.e., 3 million international units. Five days after suspending treatment bleeding occurred for 3 days. During the course of treatment it was, practically speaking, possible to observe how the ulcer in the vagina faded day by day whilst prior to treatment it was an inch in diameter; after treatment, that is to say after 23 days, the size was reduced to a small speck. Three months later the patient returned for a final examination. Menstruation had taken place meanwhile twice at regular intervals, the appearance of the vagina was quite normal. After a further 6 months the patient returned to the clinic and made the statement that—

'After our treatment, menstruation had been regular for 5 months, the next expected menstruation, however, failed to occur and, shortly afterwards, brownish-coloured discharge came from the vagina. Two ulcers were found this time in the vagina, one very nearly in the same position as the former ulcer, a second one in the vaginal cavity'.

Also this time an attempt at local treatment outside the clinic proved unsuccessful. We have treated the patient for the new ulceration only with this hormone and not locally. 600,000 mouse units (3 million international units) were administered in 24 days. After treatment, the ulcers healed completely. The patient, carried out after some time showed the vagina in a perfectly normal state.

Conclusion.—We have discovered a new kind of ulceration in the vagina so far unknown which, we consider, is due to ovarian hormone dysfunction. After unsuccessful attempts to heal the ulcers by applying local treatment, we have been able to cause the ulcers to disappear within a very short time by administering a sufficiently high dosage of follicular hormone, viz, 'progynon B in oil'. Our observations are not only interesting because they concern a rare case, but it seems that this particular case opens a so far unknown field of new indications for ovarian hormone therapy in the treatment of vaginal diseases.

The Criteria of Cure of Gonorrhœa in the Male

By AMBROSE J. KING, F.R.C.S. (Eng.)

(Abstracted from the *Journal of the American Medical Association*, Vol. CIV, 19th January, 1935, p. 178)

THERE is no phase of the management of cases of gonorrhœa that gives rise to more anxiety to the clinician than the period of probation preceding the decision as to cure. There are few errors that may be fraught with such disastrous consequences to the patient and his family, and to the reputation of the doctor, than an error in this important decision. Yet only too commonly it is found that, without adequate thought and without careful observation, this heavy responsibility is readily and lightly accepted.

In the time at my disposal I propose to enumerate the various points that must be considered in approaching such a decision, to give my views based on clinical observations in conjunction with certain improved pathologic tests, and to provoke discussion of those controversial points by which new light may be thrown on this old problem.

The tests of cure may with propriety be divided into two chronological groups, the classic and the modern. The classic group of tests are in the main clinical and imply a searching physical examination of the lower urogenital tract. Briefly, the requirements are an absolutely clear urine both by gross and by microscopic tests, negative endoscopic examination, absence of any evidence of inflammation in the urethra, testes, prostate and seminal vesicles, and a prostatovesicular fluid containing no organisms and not more than 5 white cells to the high power field. These requirements sound reasonable enough, yet it is my belief that a majority of patients affected with gonorrhœa cease treatment before achieving these classic standards of cure. Of those who measure up to these requirements many have been found, on follow up, to develop recurrences or metastatic lesions or to infect a sexual partner. It has become more and more obvious, as apparently cured cases are followed over long periods, that the classic tests furnish a most insecure index of cure. In the past many attempts have been made in the direction of greater accuracy in diagnosis of residual or latent infection; thus, the complement fixation and cultural methods are quite old—actually the complement fixation test was introduced in 1906. It is only in recent years, however, that intensive work all over the world

has led to the perfection of the complement fixation and cultural methods, thus providing a secure pathologic test of cure.

These modern tests demand a high degree of accuracy and experience on the part of the pathologist. They are of course complementary to the clinical tests and in no wise supplant them.

CULTURAL TESTS

Experience shows that cultural tests of the prostatic fluid alone are not reliable. Every effort should be made to obtain as much as possible of the contents of both prostate and seminal vesicles.

Much recent clinical and pathologic evidence points to the fact that infection of the seminal vesicles occurs in a considerably higher proportion of cases than is generally stated. A detailed discussion would be out of place here, but at least the careful microscopic and cultural examination of both fluids requires no extra effort and will give more accurate results.

The technic of culturing the gonococcus from the vesiculoprostatic contents in the chronic stage of gonorrhœa is due to the work of Dr. Orpwood Price, pathologist to the Whitechapel Clinic, and has been in routine use for the last two years. The procedure is as follows: The patient passes urine and the anterior urethra is then irrigated with sterile water. The patient assumes the knee-elbow position and the prostate and seminal vesicles are massaged thoroughly. As much as possible of the expressed fluid is allowed to drop on the surface of a culture medium contained in a Petri dish. The cover of the dish is replaced and the surface is slanted in all directions so that the greatest possible area of surface is inoculated. Before inoculation the medium is kept for at least half an hour in the incubator at 37.5°C. and is replaced immediately after inoculation. The culture is incubated for five days; it is premature to examine for gonococci before this period has elapsed. A variety of organisms may be present but the most constant feature is a profuse growth of *Staphylococcus albus*. Owing to the strong secondary growth, the gonococcus colonies may be difficult to distinguish without the use of a differential stain. For this purpose the oxidase reaction is employed.

The oxidase reaction was first used for differential diagnosis in bacteriologic work by Gordon and McLeod in 1928 and was adapted by Price to the isolation of the gonococcus in mixed culture in 1929. Briefly, the test depends on the interaction of the oxidizing ferments in certain organisms and in this case 1 per cent potassium permanganate solution in mine hydrochloride in distilled water, which produces a colour reaction. The solution should be freshly prepared.

This solution is poured over the surface of the medium so that it comes into contact with all the surface growth. A positive reaction is shown by certain colonies developing a pink coloration, which deepens through shades of purple to jet black in about thirty minutes. These colonies can then be picked off and stained by Jensen's modification of Gram's method, when they will be seen to consist of Gram-negative diplococci morphologically indistinguishable from gonococci. These are always closely associated with staphylococci, which in the first three days of incubation mask but do not inhibit their growth. Indeed, one of the most interesting features of cultures prepared and examined in this way is the appearance that is constantly seen of the gonococcus colonies growing up through the larger colonies of *Staphylococcus albus*.

The oxidase reaction is not, of course, a specific test, and other members of the neisserian group give a positive reaction. Of these only *Micrococcus catarrhalis* gives a closely similar reaction; but this organism is rarely found in the genital tract.

False positive reactions are usually given by a thin filiform type of *B. coli*, as well as by *B. subtilis*, but

these are easily distinguished by microscopic examination of the organisms when picked off the plates. If difficulty arises it is possible to make an antigen from subcultures and to titrate against a known antiserum.

Culture tests carried out according to this technic have proved most reliable and most informative. Its routine use throws light on many clinical points that have been obscure hitherto, and there is no doubt that it constitutes a very considerable advance in the methods of diagnosis of gonorrhoea in the chronic stage. As a test of cure it is invaluable.

It must be emphasized that one negative test is never sufficient and, although this cultural examination has proved to be the most delicate and reliable of tests, it can be accepted as a criterion of cure only in conjunction with negative clinical observations and the other negative pathologic tests.

In our test of cure we apply this test monthly during the period of observation without treatment. A series of four negative tests would be the minimum that could be regarded as satisfactory. In a series of 100 patients without symptoms the test was positive in 100 per cent. What evidence have we for asserting that the Gram-negative diplococcus which we recover in our cultures is the gonococcus?

Apart from the skill and experience of our pathologist, the evidence is threefold:

1. The oxidase reaction within the limits I have indicated is specific for this type of organism.
2. The titration of an antigen made from subcultures of the organism against a known gonococcus antiserum will give a positive result to the complement fixation test.

3. We make every endeavour to examine and test the husbands of married women who attend our clinic for vaginal discharges which are clinically and bacteriologically gonococci.

It is a frequent experience that the husband of such a patient has no signs or symptoms of gonorrhoea but gives a history of urethritis some years previously. In such cases we are able, almost invariably, to recover this organism in vesiculoprostatic culture.

THE COMPLEMENT FIXATION TEST

The complement fixation test for gonorrhoea is an invaluable aid in all stages of the management of gonorrhoeal cases.

In 1933 Price introduced a new antigen and improved the technic by using more concentrated serum. As the result of his work the sensitivity of the test is much improved and its value as a criterion of cure is enhanced.

False positives by 'cross-fixation' for practical purposes do not occur and we find that a positive reaction in the serum of a patient who has not been treated with gonococcus vaccine is an absolute indication of a persistent focus of infection with the gonococcus.

In a series of cases treated with gonococcus vaccine it was my experience that when cure could be established the complement fixation test became negative within six weeks of the cessation of vaccine administration. A positive result after this interval invariably indicated residual infection.

On the other hand a negative serum result to the complement fixation test, even in the symptomless patient, can never be accepted as reliable evidence of cure or anything more than a sign of good progress and efficient drainage. In many cases we are able to demonstrate the gonococcus in the secretions long after the test has become and has remained negative.

Some variation in the strength of the fixation test is to be expected in the period that precedes cure, and no single negative reaction should be regarded as conclusive serologic evidence. It is our custom to perform the test at the beginning and at the end of our period of observation and testing. It is a common experience that, when treatment is prematurely discontinued and the patient remains under observation,

the fixation test will again become positive, thus indicating a persistent focus of infection.

A provocative diet including alcohol is of assistance in the final stages. I have had no satisfactory results from provocative injections of vaccine or from provocative urethral instillations.

SUMMARY

1. No investigation as to cure need be undertaken in the gonorrhoeal patient who has a persistent urethral discharge or whose urine shows evidence of infection. To this main principle there may rarely be exceptions.

2. Palpation of the prostate is seldom of much assistance in the treated case. Palpation of the seminal vesicles is likely to give some positive information, but this is of little value when vesiculitis has been recognized and treated.

3. The macroscopic examination of the vesicular fluid and the microscopic examination of the vesicular and prostatic fluids are of great importance. Unsatisfactory microscopic tests are strong evidence against cure.

4. Vesiculoprostatic culture by Price's method constitutes an important advance in accurate diagnosis. The test repeated at monthly intervals over a period of time constitutes the absolute criterion of cure when all other tests have proved satisfactory.

5. Recent improvements in the complement fixation test for gonorrhoea have increased its sensitivity and enhanced its value in testing for cure.

6. A positive serum result in a patient who has not received injections of gonococcus vaccine within the preceding six weeks is reliable evidence against cure.

7. Negative blood serum results on successive occasions in the course of treatment are evidence of efficient treatment but not necessarily of cure.

8. A provocative diet, including alcohol, is sometimes of value as a preliminary to the final series of tests and should be employed.

CONCLUSION

Let me review the evidence against cure in a clinically well patient. A negative complement fixation test may merely mean efficient drainage; it can and does occur when even smears are positive. What is the meaning of repeated positive cultures? I feel that while striving for accurate and infallible criteria of cure, we have arrived at the unenviable position of having apparently proved that cure is very much more difficult of achievement than is generally realized.

Further, it appears that the clinically well patient, having established a biologic equilibrium with his gonococci, retains the power of transmitting virulent infection to his sexual partner. Despite the work, time and thought given by us to this subject, I do not feel that we have arrived at conclusions which warrant more definite formulation. I do feel, however, that we have been able to establish the fallacies of previously accepted standards of cure. This paper is presented as an account of the work of the White-chapel Clinic up to the present, so as to set forth our observations and difficulties and in the hope of enlisting co-operation and help in the work that lies ahead in the attack on the bristling problems of this ancient social menace.

The Significance and Treatment of Cough

By J. BROWNING ALEXANDER, M.D., M.R.C.P.
(Abstracted from the *Practitioner*, Vol. CXXXIV, January 1935, p. 83)

THE TREATMENT OF COUGH

THE treatment of cough naturally depends upon a correct diagnosis having been made. The indiscriminate use of cough mixtures is often harmful, as it may tend to mask the true underlying cause. It is very common to meet with patients who have for

many months or even years been content to have their cough kept in check by some soothing cough mixture, only to have discovered later well advanced pulmonary disease, which, had it been detected in its early stages, might have yielded to treatment.

When dealing with the treatment of cough from what may be called local causes, it is obvious that a cough due to enlarged tonsils and adenoids must be treated surgically—by removal of the tonsils—and adenoids. Again, the long uvula may be cut, though once more it is important to realize the danger of making this diagnosis before other causes have been carefully excluded. For the pharyngitis, which is often secondary to dyspeptic conditions, remedies liable to correct the latter and possibly advice to the patient regarding diet, avoidance of alcohol or tobacco in excess will be the best methods of dealing with the pharyngeal cough.

In laryngitis, however, and tracheitis, relief can usually be obtained by a mixture to lessen congestion of the inflamed mucous membrane and promote secretion and thus lessen the painful character of the cough. Such a mixture as the following is of value:—

R̄ Sodii bicarbonatis	..	gr. xv
Tincturæ ipecacuanhæ	..	℥ viiss
Syrupi toluani	{ aa	.. ℥ xxx
Syrupi scillæ		
Spiriti chloroformis	..	℥ x
Infusum senegæ ad	..	℥ i

One ounce every 4 hours until the sputum has become free.

For this condition also inhalations are useful. The following are examples:—

R̄ Tincturæ benzoini	Sixty minims to the pint of
compositæ.	water.

Or to this may be added:—

Three minims each of menthol and oil of eucalyptus.

Another remedy which is of value for relieving the cough of laryngitis and tracheitis is the application round the neck of antiphlogistine or warm olive oil.

In the early stages of bronchitis, when the cough is troublesome, painful and non-productive, the same mixture as recommended for laryngitis may be used with benefit. The following mixture is also useful:—

R̄ Vini antimonialis	..	℥ xv
Ammonii chloridi	..	gr. x
Spiriti chloroformis	..	℥ x
Syrupi aurantii	..	℥ lx
Aquam camphoræ ad	..	℥ i

This should also be discontinued, probably after two or three days, when the sputum becomes free.

The cough which is a feature of the later stages of bronchitis, when expectoration is copious, calls for drugs which are of the stimulating expectorant type—a mixture such as the following is of use:—

R̄ Ammonii carbonatis	..	gr. v
Tincturæ nucis vomicæ	..	℥ viii
Tincturæ scillæ	..	℥ xv
Aquam ad	..	℥ i

or alternatively—

R̄ Ammonii carbonatis	..	gr. v
Tincturæ scillæ	..	℥ xv
Tincturæ opii camphoratæ	..	℥ xx
Infusum senegæ ad	..	℥ i

A very useful prescription for children suffering from a cough which is just becoming loose is the following:—

R̄ Tincturæ ipecacuanhæ	..	℥ ii-v
Tincturæ opii camphoratæ	..	℥ v-x
Potassii nitratis	..	gr. ii
Oxymellis	..	℥ xxx-lx
Aquam ad	..	℥ cxx

With regard to the cough of pulmonary tuberculosis the treatment of it will depend upon whether it be of

a useful or useless type. In the case of the latter, the patient can often be trained to suppress the act, but in these circumstances it is necessary to prescribe some sedative drug, especially when the useless cough prevents sleep. Such a mixture as the following is worthy of trial.

R̄ Heroin	..	gr. 1/12
Syrupi pruni virginianæ	{	℥ xxx
Syrupi codeinæ		
Aquam ad	..	℥ ss

or the following prescription may be found even better:—

R̄ Heroin	..	gr. 1/12
Codeinæ	..	gr. 1/8
Acidi sulphurici diluti	..	℥ ii
Glycerini	..	gr. x
Syrupum toluatum ad	..	℥ lx

For this type of cough dry inhalations are often of use and for this purpose the most useful drugs are creosote, menthol and rectified spirits in the following proportions:—

R̄ Menthol	..	℥ lx
Creosot	..	℥ lx
Spiriti vini recti	..	℥ ss

A few drops sprinkled on a mask and inhaled for a few minutes has often a soothing effect.

When, however, the cough is useful, in as much as expectoration has to be brought up every endeavour must be made to loosen it—and here, as in the case of bronchitis, ammonium chloride and antimony are invaluable. The prescription already detailed for the early stages of bronchitis may be used in this case also.

When one is dealing with fibrosis of the lung, either due to pulmonary tuberculosis or other causes, the cough is usually associated with marked dyspnoea and often is in great part caused by failure of the right ventricle of the heart. Therefore relief will be better obtained by given cardiac tonics, such as digitalis, nux vomica, than by sedative cough mixtures. Some such prescription as the following is in common use:—

R̄ Tincturæ digitalis	..	℥ v
Ammonii carbonatis	..	gr. v
Tincturæ nucis vomicæ	..	℥ v
Spiriti chloroformis	..	℥ x
Aquam ad	..	℥ i

In some severe cases Nativelle's granule 1/600th two or three times a day may prove successful in diminishing the cough.

Belladonna is of definite use in the treatment of certain types of cough in which an anti-spasmodic effect is desired. The following prescription may be taken as an example:—

R̄ Tincturæ sambul	..	℥ xv
Tincturæ stramonii	..	℥ x
Tincturæ belladonnæ	..	℥ v
Spiriti chloroformis	..	℥ xv
Aquam ad	..	℥ ss

Finally it may be again emphasized that the successful treatment of cough will depend upon a correct diagnosis of its cause having been made.

Recent Trends in Diphtheria Prophylaxis

By J. C. SAUNDERS

(From the *Irish Journal Medical Science*, March 1935, Sixth Series, No. 111, p. 117)

In this paper I am confining myself entirely to our own experience in Cork City, which now extends over a period of practically five years and embraces observations on some 12,000 children who have passed through our hands in that time. The amount of

material and the duration of the period under review induce a certain amount of confidence in expressing opinions which have been wanting hitherto. I do not propose to go into details but will confine myself to a more or less broad statement of the observations on which our present procedure is based, except in such as those in which a more detailed examination appears to be necessitated.

A number of different prophylactics have been on the market, and in assessing the values of these it seems to me that the best way of approaching a solution is to consider what I may term our apparent failures and to examine their relationship to the particular antigen used. When we commenced immunization the prophylactic of choice was toxoid-antitoxin, which was favoured because of its good antigenic power and the complete absence of any serious after-effects which has always been associated with it. This was the prophylactic favoured in England and the United States, while Ramon's anatoxin (which must be distinguished from the more recent formol-toxoid) was most in use on the Continent. There has been little to choose between these prophylactics.

In the course of time there began to crop up amongst the children treated by us cases reported as suffering from diphtheria. We are fortunate in Cork in this respect that we are a fairly large but compact population, and, therefore, it has been comparatively easy to exercise supervision over suspects. Careful records have been kept of every such case and we have learned a great deal from them.

It is necessary at this stage to go into a few figures, and I have to stress that these relate only to the end of 1933. We have not yet had the time to analyse fully those of 1934, which I may state have been the best for any year so far as regards numbers treated and results are judged by the Schick test. There is no doubt, therefore, that when they do come to be included they will influence the total results in an even more favourable light. So far, the total number of treated cases who have been reported as suffering from diphtheria amounts to 132. Of this number, 92 are excluded from the computations, as in 69 of them the diagnosis was not confirmed and in 23 treatment was incomplete. This leaves a residue of 40 cases which we have to consider in a little further detail. Of the 40, two were primary negative Schick reactors, and 13 secondary negative reactors (i.e., after undergoing a course of treatment). There were, therefore, 25 who had not been Schick-tested after treatment, and the essential criterion of a successful course of treatment is a negative Schick reaction after such a course. Properly speaking, such cases should, therefore, be excluded on this ground.

Of the two primary Schick-negative reactors there is little to be said. It is well known that the liability of natural immunes (as judged by the Schick test) to relapse is very slight indeed. Our two cases represent a proportion of 0.13 per cent of the total known negative reactors in this category (or slightly more than 1 in 1,000), but the proportion to the total natural immunes in the whole population must be very much smaller. The 13 secondary Schick-negative reactors occurred amongst a group of 3,402 children who completed the full course of treatment and underwent a subsequent Schick test. This represents a proportion of 0.38 per cent (or 3 per 1,000), but here again the figures are fallacious, as a very considerable number of children who underwent the full course failed to present themselves for the final test. The actual number of such cases was 4,058 and, since our experience over five years has shown an average of 90 per cent of treated children to be negative, it must be assumed that at least 3,650 of this group were negative. These added to the known negative reactors make a total of 7,054 who were presumably negative, and 13 relapses amongst this group represents a proportion of 0.18 per cent. The number of relapses amongst the non-tested group (7,460 cases) was 25, representing a proportion of 0.35 per cent. I may add that while this figure

includes all the relapses which occurred up to the end of 1934, they do not include the number of children dealt with in that year. The latter number some 3,000 and, if included, would have the effect of materially reducing these figures.

We have, therefore, three series of figures: (1) natural Schick-negatives, 1 per 1,000; (2) secondary Schick-negative reactors roughly 2 per 1,000; and (3) untested children, 3 per 1,000. The average incidence of diphtheria per 1,000 of the population over the past five years was 10.4 per 1,000, so that from this point of view it is apparent that although active immunization has not hitherto been absolutely effective, the liability of immunized children to contract diphtheria is very much less than that of non-immunized children. The figure for the incidence of diphtheria among non-immunized is, in reality, very much higher than indicated above and would be more clearly shown if the population could be divided into two separate groups, immunized and non-immunized. This was done in 1931 and it was then found that the incidence of diphtheria in untreated children was no less than 25.6 per 1,000 (as compared with 2.3 per 1,000 in the treated groups). It is well, at this point, to emphasize the fact that so far, after some six years' experience of immunization, we have not had to record a single death from diphtheria among immunized children, who now comprise the relatively very large group of some 12,000 in Cork, notwithstanding the extreme virulence which has characterized the disease here for the past few years as evidenced by the fatality rates which have ranged from 15 to 22 or 23 per cent. During the same period 180 untreated children died from the disease.

Of the total 40 relapses with which we are now dealing, 34 occurred amongst children who were treated with toxoid-antitoxin and four amongst those treated with alum-toxoid; the remaining two had no treatment, being found negative on the preliminary test. What proportions these represent of the respective groups I have not been able to compute, but the relapses amongst alum-toxoid treated children have been relatively far less frequent than those amongst the other group. This question of relapses has been the subject of deep consideration amongst the producers of prophylactic agents and has led to a keen search for a more reliable antigen than toxoid-antitoxin. A number of such agents has been produced during the past few years and, in our experience, they have been so obviously superior to toxoid-antitoxin that we have now completely abandoned the use of that product. In what follows I will discuss the relative merits of these new antigens.

Alum-toxoid

In our hands this product has been very satisfactory indeed. Four relapses have been recorded, but it is necessary to point out that in two of them the batch used was the first produced. It was possessed of a very low *Lf* value and on further investigation was found to possess little or no antigenic power. It was withdrawn shortly after introduction (and after we had treated nine cases with it). One of the two remaining cases was ill three days before receiving antitoxin treatment, and when I saw him on the fourth day he was sitting up and had actually been out of bed and appeared to be none the worse for it. Obviously the infection in his case was of a very mild character. This case is of some interest. He was one of a number of boys who were affected in a very severe outbreak of diphtheria in a local school (in which two died) and had been sitting next to the acute carrier who caused the outbreak. In every one of these cases the organism was of the *gravis* type.

In the earlier batches of alum-toxoid unpleasant reactions and more or less marked indurations occurred in a number of cases. This difficulty now appears to have been largely overcome in the new alum-toxoid which has been issued by the Wellcome Research Laboratory, and we have been obtaining extremely good

results with a single dose. Whereas with toxoid-antitoxin one had to administer three doses and wait six months before testing, we now find that over 90 per cent of our cases are negative in five weeks after a single dose of alum-toxoid. This is, of course, an enormous advantage and I have no doubt that alum-toxoid will be the prophylactic of choice in the near future.

Formol-toxoid

In the interval between the withdrawal of the old alum-toxoid and its recent reintroduction there came on the market a new prophylactic under the designation of formol-toxoid (or F. T.). F. T. differs from the anatoxin or toxoid of Ramon in that it was prepared from a much more potent toxin as measured by the flocculation test. Mr. Pope, of the Wellcome Research Laboratory, was responsible for this antigen. The greatly increased potency of the original toxin from which it is prepared is due to improved methods of cultivating the diphtheria organism. In actual practice we have found this prophylactic to be highly satisfactory. Two injections at intervals of three weeks to a month are sufficient to induce immunity in over 90 per cent of cases as judged by the Schick test administered within six weeks of the last dose. The liability to reactions is, however, somewhat higher than with T. A. M., and it is not safe to administer it to children over eight years of age without a preliminary Moloney test to detect reactors. This is the accepted teaching, but I must say that in our experience we have had very few complaints. Of course, we have carried out the Moloney test where indicated, but still a good many older children have been treated without this test and the reactions do not appear to have been very much more frequent than with T. A. M.

F. T. is possessed of a very high degree of immunizing power, far greater than T. A. M., induced with much more rapidity and with two doses, which is of a great advantage. It is considerably cheaper than floccules and can be safely administered to any child of six years or under without fear of reactions. I have never seen reactions in children of these ages and have no hesitation in using it for them. We have been using this antigen for the past year and a half and have dealt with some 1,700 cases. So far we have had no relapses with it, but the time interval is still too short to judge of its merit in this respect. There is no doubt, however, that F. T. is a great advance on T. A. M.

Floccules

The prophylactic known under this designation, generally referred to as T. A. F., has been known for a number of years. When toxoid and antitoxin are mixed a flocculent precipitate is thrown down which has been found to be possessed of a high degree of immunizing power and constitutes the antigen now under discussion. From the point of view of freedom from liability to cause reactions T. A. F. is undoubtedly the best of all prophylactics so far produced, but its high cost has operated against its general use up to the present. Where expense is not a consideration it is the antigen of choice. Hitherto, it was thought that three injections were necessary, but now it has been found that two, properly spaced, are sufficient to immunize the great majority of cases.

The proper spacing of doses of prophylactics is a matter of considerable importance. For instance, let us say, that 1 cubic centimetre of a prophylactic will induce a certain degree of immunity (as measured by the amount of circulating antitoxin in the blood) in a given period, say twelve weeks, it has been found that if administered in two fractions, the second being given three weeks after the first, there is a very rapid acceleration in the formation of antitoxin after the second dose, so that the maximum amount is reached in six or seven weeks. Two doses of T. A. F. at intervals of three or four weeks are more effective than three doses at intervals of a week.

We have had a good deal of experience with T. A. F. over the past year in connection with the use of F. T.

Any children yielding a positive Moloney test are treated with this product and the results as judged by the subsequent Schick test have been universally satisfactory. Again, in this case the test is carried out six weeks after the last dose and, as in the case of F. T., there have been no relapses so far. But here again the remarks concerning the length of the time interval apply. It is too soon yet to judge, but one has the distinct impression, from this point of view also, that both of these antigens are a decided advance on T. A. M.

Summary

It is not possible to say with certainty what is likely to be the prophylactic of choice in the immediate future. One thing however is clear, viz, that the use of toxoid-antitoxin (T. A. M.) should be discontinued. To date one can say roughly that half of our cases have been treated with this antigen, while of all our relapses no less than 90 per cent fall into this group. Obviously, therefore, from the point of view of permanence it falls far short of the other agents. But these figures must be taken with caution, as the period over which the factors making for relapse have had time to act has been greater with T. A. M. than with the others. On this score, however, alum-toxoid has clearly proved far superior. One can, therefore, definitely recommend that T. A. M. should be dropped, and this has been the experience everywhere. Where alum-toxoid or floccules have not been adopted, T. A. M. has been completely supplanted by formol-toxoid.

As regards formol-toxoid, it can be used without hesitation in all children under six years. In the very few cases in which reactions occur they are invariably very mild and in such the second dose may be administered in T. A. F. (floccules). It is a very suitable antigen for such children and has the merit of cheapness and absolute freedom from toxicity. There is no toxin in its composition and, consequently, there is no liability to dissociation with the setting free of toxin which occurred with the old toxin-antitoxin (T. A. T.) and which caused a number of disasters on the Continent and elsewhere. T. A. T., of course, must be distinguished from T. A. M. which also has no toxin in its composition.

F. T. is possessed of somewhat higher antigenic power than T. A. F. (floccules) but, as stated above, where expense does not matter the latter is the antigen of choice. From the point of view of the private practitioner T. A. F. would appear to be the ideal prophylactic. Its high antigenic value and almost complete freedom from reactions mark it out especially in this respect. Two doses at intervals of a month or three weeks (instead of the three doses formerly recommended) are quite sufficient, and this fact materially reduces the cost of inducing immunity. In the case of adolescents and older people T. A. F. is the only antigen that can be recommended.

As regards alum-toxoid or, as it is now termed, alum precipitated toxoid (A. P. T.), the fact that a single dose is sufficient to confer immunity in the vast majority of cases is an overwhelming advantage and makes it a serious contender for choice in any circumstances. Two disadvantages have been urged against it: (1) the liability to cause serious reactions and (2) the tendency to the formation of indurations at the site of injection. As regards the former it can be said that with the new product this liability has been enormously reduced and that when reactions do occur they are definitely less than those formerly associated with the old A. M. T. With regard to induration, many observers regard this phenomenon as a very decided advantage. The efficacy of A. P. T. is dependent on the slow and continuous absorption of the antigen from the site of injection whereby there is a prolonged stimulus to the formation of antibodies in the tissues. This in its turn is due to the particulate matter, the precipitate, which holds the antigen in suspension in the case of alum-toxoid.

In the case of T. A. M., which is a perfectly clear solution, it has been shown that the first dose is almost completely eliminated from the body and with great rapidity, the second more slowly, while it is the third that acts as the main stimulus to the formation of antibody. The advantage of an antigen which is retained at the site of inoculation is at once apparent, and the whole rationale of alum-toxoid is based on this observation which was first noted in horses. It was found that a far more potent tetanus toxin could be produced by inducing a sterile abscess at the site of injection of the toxin. Tapioca grains were originally used, and eventually insoluble alum salts. The technique here evolved gradually came to be applied to human beings, almost entirely by the workers of the Wellcome Research Laboratories, and the result has been the modern high potency A. P. T., which holds very great promise indeed.

From the point of view of the public health worker endeavouring to immunize the maximum number of children it is alone in its field. Hitherto the leakage caused by cases failing to return for completion of treatment has been an almost insuperable hindrance to

mass immunization. This difficulty now appears to have been overcome, so that one can look forward with a high degree of confidence to the future that the effect of immunization on the general incidence of diphtheria will be much more marked than it has been.

To the private practitioner also, it would seem to me, the inherent advantages of a prophylactic such as A. P. T. must be very alluring. The induction of immunity by a single dose in the majority of cases is a factor that cannot easily be outweighed, but I would impress upon my readers that the A. P. T. I have in mind has only quite recently come on the market. In my opinion, the brands hitherto obtainable are not the same, and have been issued with undue precipitancy. I can testify to the extraordinary care and caution which have been exercised by the original producers of A. P. T., the Wellcome Research Laboratory, and to the enormous number of animal experiments which have been carried out in connection with it notwithstanding all of which, up to quite recent times, they have not been satisfied that they had produced an article suitable for general release.

Reviews

THE MEDICAL ANNUAL: A YEAR BOOK OF TREATMENT AND PRACTITIONER'S INDEX. Edited by H. L. Tidy, M.A., M.D. (Oxon.), F.R.C.P., and A. R. Short, M.D., B.S., B.Sc., F.R.C.S. Fifty-third Year. 1935. John Wright and Sons, Limited, Bristol. Pp. cl plus 600, with 141 text illustrations and 63 plates, plain and coloured. Price, 20s.

THIS annual review of recent advances in the medical sciences will be as welcome as it usually is, both to the practitioner, who has little time—or opportunity in most instances—to study current medical literature, and to the specialist, who usually has a myopic tendency which he is quite ready to correct when correction is made easy.

The year 1934 was not notable for any conspicuous advances, and the task of picking out sections for special mention is thus not made easy.

The heading *anæmia* is apparently reserved for pernicious *anæmia*, other *anæmias* being placed under blood diseases. The reason for this is not quite clear; though admittedly pernicious *anæmia* is not a blood disease, in that the blood is more sinned against than sinning, this is true of the majority of the other *anæmias*. [We hope that this favouritism shown towards pernicious *anæmia* will not increase the feelings of resentment that must already exist amongst the *anæmias* at the undue attention that has been paid to it during the last decade. However, let us remind them that nothing has done more to raise the status of *anæmias* in general than these investigations into the *ætiology* and treatment of 'p. a.']. There is little new to record this year, except that emphasis is being laid on the superiority of parenteral over oral liver extract. A liberal resumé of Wintrobe's paper on normal American standards is given. It is quite time that the older standards were entirely abandoned, as it is becoming increasingly apparent that, although the normal hæmoglobin may be less in Great Britain than in America, Haldane's figure of 13.8 grammes per 100 c.cm. is ridiculously low. Standards for India have still to be worked out, but it is certain that the normal hæmoglobin is above 13.8 grammes and that the 'thin' blood of the dweller in the tropics is a myth.

Attention is drawn to the obvious fact that iron will produce at any rate temporary improvement in 'splenic *anæmia*', as it will in any condition where there is loss of blood and consequent 'siderosis'. The writer in this section seems to think that in the past splenectomy has been undertaken rather too readily in

this condition. We do not agree, but we do consider that the surgeon who fails to give a course of large doses of iron before the operation is scarcely being fair to his patient. A paper on the indications for splenectomy is quoted at some length and there is a plate showing the technique of splenectomy; this plate is useful, but it will fill with envy the Indian surgeon who seldom has the pleasure of removing such a neat, non-adherent and moderate-sized spleen.

The advances in *anæsthesia* have been mainly in the technique of administration and in this section there are a number of useful illustrations of apparatus. Intravenous *anæsthesia* has obviously come to stay and some simple equipment for its easy administration will soon be an essential part of the general practitioner's equipment.

Some useful work on asthma is reported. The Therapeutic Trial Committee of the Medical Research Council have initiated investigations into the value of ephedrine and pseudo-ephedrine; the latter is of value mainly in alleviating minor symptoms and is of little value in the severe attack. Otherwise, the year has brought forth the usual batch of 'specifics'.

A statistical enquiry into the question of the increase of cancer is reported. The evidence points to an actual increase, but not to the extent that the crude death rates indicate. The greater part of this section deals with the radium treatment of cancer.

The use of the barbiturates in epilepsy is discussed at some length. Phenobarbitone is recommended on the grounds of cheapness. It is as effective as the proprietary preparations that were tried.

The work of Böhler of Vienna is influencing the treatment of fractures throughout the world and recently it seems to have captured the attention of British surgeons in particular. This influence is well reflected in this useful section on fractures in this book.

Thyroidectomy in heart failure can almost claim to be a new procedure. During the last two years a number of papers on the subject have been published; these are reviewed. So far the operation has been mainly confined to patients in whom the immediate prognosis was bad. Many of them have been much relieved.

Under the heading of hypnotics a few of the skirmishes in the battle of the barbiturates are reported. Whether the extreme pessimism of the two noble knights, Sir William and Sir James, is justifiable, time will presumably show, but meanwhile in Great Britain these drugs are placed in schedule II and cannot be

obtained except on the prescription of a doctor. It is alarming to realize that in India they can be purchased by the pound by anyone who has a troublesome relative with a toothache!

Statistics on the value of anti-pneumococcal serum are still piling up. Its value in type I, and to a less extent type II, strain infection seems to be firmly established. It is, however, depressing (for some of us) to read that serum treatment does little to lower the death rate in patients over 40 years of age; a time honoured 'friendship' is not therefore to be broken by modern therapy.

In the dietetic world vitamin A is having rather a thin time. Its reputation as an anti-infective vitamin seems to have been shaken by recent work; it is still claimed that in the case of actual deficiency infections, especially respiratory, are more frequent; but few diets appear to be thus deficient, and you can apparently eat carrots until your serum runs red and you will still get a cold in your nose.

Tropical diseases are as usual dealt with in a very satisfactory manner, by Sir Leonard Rogers. In the malaria section all the recent work on the synthetic anti-malarials, in India and elsewhere, is reviewed, as also is the entomological, epidemiological and parasitological work done under the auspices of the Indian Research Fund Association. There is reference to the report of the League of Nations' Malaria Committee and the criticisms that were voiced in this journal are repeated.

By way of conclusion we may say that this year's medical annual still provides the answer to the medical practitioner's question 'How can I spend twenty shillings to the best advantage to myself and to my patients?'

L. E. N.

GYNÆCOLOGY FOR STUDENTS AND PRACTITIONERS.—By T. W. Edon, M.D., C.M. (Edin.), F.R.C.P. (Lond.), F.R.C.S. (Edin.), F.C.O.G., and C. Lockyer, M.D., B.S. (Lond.), F.R.C.P. (Lond.), F.R.C.S. (Eng.), F.C.O.G. Fourth Edition. By H. B. Whitehouse, M.B.M.S. (Lond.), Ch.M. (B'ham), F.R.C.S. (Eng.), F.C.O.G., F.A.C.S. (Hon.). 1935. J. and A. Churchill Ltd, London. Pp. xviii plus 964, with 36 coloured plates and 619 illustrations in the text. Price, 38s.

We are pleased to welcome the fourth edition of Edon and Lockyer's *Gynaecology* edited and revised by Beckwith Whitehouse. The general plan of the volume is unaltered but is entirely modernized. It is confidently recommended to the advanced student, the practitioner and to those who are studying for a higher diploma. It is an up-to-date, lucid and reliable work. The illustrations are numerous and clear; several new ones have been added. The number of coloured plates has been increased to thirty-five; they are beautifully executed. We would suggest, however, that suitable paper should be provided to protect them; we found some adherent to the opposite page. The printing and binding leave nothing to be desired.

More cosmopolitan views are given than are usually found in British textbooks. It is just possible that, in the endeavour to give the latest word on the physiology of the female sex organs and on disorders of menstruation, insufficient space is allotted to the full discussion of more urgent conditions. Ketogenic diet is not mentioned in the treatment of *B. coli* pyelonephritis. We think it is a pity that the differential diagnosis of many conditions should be grouped together in part IV and omitted altogether from the original heading. We feel that the description of any condition is quite incomplete without its differential diagnosis.

The terms, menostaxis and metrostaxis are introduced to supplement menorrhagia, metrorrhagia and epimenorrhœa. A chapter on contraception appears for the first time. We are pleased to see this subject definitely taken into medical hands; it is well and concisely dealt with. We beg to differ, however, with the statement

that the vaginal route gives adequate access for the sterilization of multiparæ. We have known of three women in whom pregnancy followed upon this procedure although the operations were carried out by a skilled gynaecologist. The section dealing with sterility is well done but we think that an unduly optimistic view is taken of the reliability of the results of insufflation of the tubes by air or gas.

Part III deals with regional gynaecology; it is excellent. Part V is devoted to operative gynaecology and proceeds on the same general principles as previous editions. There are certain additions which we are very pleased to see, such as the Manchester operation for prolapse. There is another which we do not welcome—the interposition operation for prolapse introduced by Wertheim thirty-six years ago. We have seen only unpleasant results follow upon this procedure—unpleasant for the operator as well as for the patient. We have therefore never performed it and consider that the warning issued by Graves on this subject should be added to every description of this operation. With this one exception, the operations described are reliable, amply explained and clearly illustrated.

S. A. McS.

MIDWIFERY.—By Ten Teachers. Under the direction of C. White, M.D., B.S. (Lond.), F.R.C.P. (Lond.), F.R.C.S. (Eng.), F.C.O.G. Edited by Sir C. Berkeley, J. S. Fairbairn, and C. White. Fifth Edition. 1935. Edward Arnold and Company, London. Pp. xi plus 740. Illustrated. Price, 18s.

The fifth edition of *Midwifery by Ten Teachers* has appeared this time, under the direction of Dr. Clifford White. All important recent advances have been incorporated. It can be heartily recommended to those for whom the work was originally designed—students reading for their final examination and the busy general practitioner. It is clear, concise, easy to read, admirably printed and profusely illustrated.

There are only a very few points which we think need revision. We have never had any success with injecting saline through the umbilical vein as a means of separating an adherent placenta; the reason is that the placenta is partially separated and the saline runs out through the separated area. The necessity of taking a catheter specimen of urine for culture, as well as cultures from the cervix and from the blood, in the investigation of pyrexia during the puerperium is not mentioned. The dose of quinine recommended for induction of labour—30 grains in three hours—is, we think, at least twice too high and definitely dangerous. Like DeLee, we have found 5 grains (and in many cases 3 grains) every two hours for three doses quite as effective. There is a misprint on page 499; 'blood vessels are opened' should obviously read 'blood vessels are not opened'.

These few points are negligible in a work of general excellence which we have the greatest pleasure in recommending.

S. A. McS.

MANUAL OF PHYSICAL AND CLINICAL DIAGNOSIS.—By O. Selfert and F. Mueller. Authorized translation from the Thirty-first German Edition. By E. C. Andrews, M.D. Second Edition. J. B. Lippincott Company, Philadelphia and London. Pp. xi plus 561, with 152 illustrations and 5 coloured inserts. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 18-12

This is an English translation of the thirty-first German edition. The work needs no recommendation as numerous editions in different languages attest to the value of this compendium of diagnostic methods and data. The facts are presented in a clear and orderly manner. The subject-matter has been arranged to accord with the course that a student can easily pursue. Anatomical and physiological descriptions have been incorporated in appropriate places. Various clinical

methods, physical signs, chemical tests and data have been furnished with omission of the non-essential and obvious things. Concise accounts of parasites, infectious diseases, glands of internal secretion and metabolism have also been included. One section has been devoted to skin diseases. The appendix contains tables on poisoning, dosage, etc. The illustrations are good and explanatory. The book will greatly fulfil the needs of the physician and student at the bedside.

Few criticisms can be offered. Under 'spleen' kala-azar has been omitted as one of the causes of its enlargement. The list of causes of enlarged liver is incomplete. The statement that kala-azar is often fatal cannot be supported in these days of improved treatment.

R N C

MEDICINE. Part IV. Catechism Series. Third Edition. 1935. E. and S. Livingstone, Edinburgh. Pp. from 281 to 380. Price, 1s. 6d. Postage, 2d.

This little book deals with diseases of the respiratory organs and of the circulatory system. Within its sphere it contains useful information. Medical students will find it a desirable companion when preparing for their oral examination. The publishers are to be congratulated on its production.

P D.

MATERIA MEDICA, PHARMACY, PHARMACOLOGY AND THERAPEUTICS.—By W. Hale-White, K.B.E., M.B. (Lond.), M.D. (Dub.), LL.D. (Edin.). Twenty-second Edition revised by A. H. Douthwaite, M.D., F.R.C.P. 1935. J. and A. Churchill, Limited, London. Pp. xi plus 552. Price, 10s. 6d.

The twenty-second edition of this book scarcely needs an introduction, for in the forty-four years since the appearance of the first edition it has become known and used by successive generations of medical students until it is probably now the most widely-known book on the subject in the English language.

This edition has been produced to keep the book abreast of advances in therapeutics especially in the sections on vitamins and biological products and to bring it into line with the new edition of the *British Pharmacopœia Codex* which was issued last year. The work has been well done by its present editor and this small volume in its rejuvenated state can be still relied on by students and practitioners to provide them with practically all they need to know on materia medica, pharmacy, pharmacology and therapeutics.

P A M

THE CLINICAL ASPECTS OF VISCERAL NEUROLOGY WITH SPECIAL REFERENCE TO THE SURGERY OF THE SYMPATHETIC NERVOUS SYSTEM.—By W. K. Livingstone, M.D. 1935. Baillière, Tindall and Cox, London. Pp. xi plus 254, with 46 figures. Price, 22s. 6d.

The last decade has seen an ever-increasing interest in the physiology and pathology of the autonomic nervous system. As yet most of the important work done is scattered in numerous papers in diverse journals and anyone who is interested has to undertake a laborious quest before he can master even the essentials of the subject. For this reason a monograph dealing with the fundamentals of the normal and abnormal functions of the autonomic nervous system is very welcome. The present work is all the more so, for it treats the problems primarily from a clinical standpoint. The book opens with a brief but most accurate and up-to-date account of the anatomy and physiology. After that each pathological condition is illustrated by clinical notes of several actual cases. This method leaves unforgettable mental pictures while at the same time it serves to bring out the variations as well as the difficulties associated with diagnosis. The views expressed are very balanced; advances are recorded while at every stage the limitations of our knowledge are emphasized. Very

valuable are the beautiful coloured plates and charts interspersed throughout the book. The various surgical procedures are all grouped in the closing chapters. One gathers the impression that the author must have been pressed for space, for many important details of technique as well as the difficulties and dangers of the operations described are omitted. Perhaps in a book intended for the average practitioner this is not a serious drawback. It is a book to be read by every practitioner and possessed by every consultant, medical and surgical.

K V K.

BACKACHE.—By J. Monnell, M.A., M.D., B.C. (Cantab.). Illustrated by Margaret Morris. Second Edition. 1935. J. and A. Churchill, Limited, London. Pp. x plus 227. Illustrated. Price, 10s. 6d.

The author has given a comprehensive account of the symptoms, diagnosis, treatment and prophylaxis of backache from the standpoint of an orthopedic physician.

The volume is a record of his own work and contains no quotations from other works or from articles already published on the subject. The author first points out the importance of taking a careful and complete history of every case. Then he insists on the search for a septic focus. Next he describes the various methods of examination of different parts, which are illustrated with line-drawings. He has also shown how to tabulate the findings of the examination so that they can be reviewed at once. Two chapters have been devoted to diagnosis and differential diagnosis of the various conditions giving rise to backache. In the section on treatment methods of movement, manipulation, massage and electricity have been described.

The book is well indexed and well produced and should prove very helpful especially in orthopedic practice.

R. N. C.

THE DIABETIC A. B. C.—By R. D. Lawrence, M.A., M.D., F.R.C.P. (Lond.). Third Edition. 1935. H. K. Lewis and Company, Limited, London. Pp. vii plus 59. Price, 3s. 6d.

This little book is intended to be used as a practical guide by patients especially to enable them to follow the author's *line ration scheme* of dieting intelligently. The present edition contains, like its predecessors, useful information of a somewhat broad and general nature and as such is likely to be of value to diabetic patients undergoing treatment.

No fundamental changes have been introduced in the present edition except that the *line ration scheme* has been somewhat modified to provide lower fat and higher carbohydrate diets when desirable.

J. P B

TREATMENT BY DIET.—By C. J. Barborka, B.S., M.S., M.D., D.Sc., F.A.C.P. 1934. J. B. Lippincott Company, Philadelphia and London. Pp. xii plus 615. Illustrated. Price, 21s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 15-12.

This is an eminently practical book; only the minimum of space compatible with giving necessary information is devoted to descriptive passages, and a larger part of the book is composed of diets arranged in lists so that one can at a glance pick out the foods recommended.

Part I is a short account of the dietetic principles to be followed in normal health which might be profitably read by both the medical profession and the lay public for it is couched in such simple language that anyone could understand it.

This is followed by a part devoted to diet under special diseases in section A is given the diseases in which diet is an essential part of treatment, and section B in which attention to diet is less important

though still worthy of consideration. A short section is devoted to dietetic suggestions for an ordinary hospital and there is a section devoted to tables giving food values, normal weights, etc., and a few selected recipes. There is a copious bibliography so that the reader is given ample assistance in acquiring further information should he feel he needs it.

This is a book which will be of great use in enabling a busy practitioner to rapidly select a suitable diet for any case and it is one that might be handed to an intelligent patient with advantage.

P. A. M.

CLINICAL PATHOLOGY AND THE TECHNIQUE OF COLLECTING SPECIMENS.—By W. Smith, M.A., M.D., B.Chlr. (Cantab.). 1935. J. and A. Churchill, Limited, London. Pp. x plus 227. Illustrated. Price, 10s. 6d.

THIS small book is somewhat disappointing for in the preface the author states that '... an attempt to describe some of the elementary principles of clinical pathology... including the apparatus required for collecting various specimens...' is made. Perusal of the book leads one to the conclusion that the attempt has not been particularly successful. So much space is devoted to descriptive passages that are so elementary and brief as to be of little use, that very little room is left for the practical information the book sets out to convey. It is not a book we can recommend.

BACTERIOLOGY AND PROTOZOOLOGY: IN MEDICINE AND PUBLIC HEALTH. (Catechism Series.)—By W. R. Logan, M.D., F.R.C.P.E., D.P.H. Fourth Edition. Part II. E. and S. Livingstone, Edinburgh. Pp. from 77 to 156. Price, 1s. 6d. Postage, 2d.

A CONSIDERABLE amount of ingenuity is required in a book of this type, where the main points in the study of the various micro-organisms and protozoa of interest to the medical profession are brought out in the form of question and answer, to give adequate information without being dogmatic and without entering into long discussions. That this has been achieved is evident from the popularity of the book which is now in its fourth edition.

It will prove of particular value to students appearing for an examination. Its chief danger, as in all books of this type, is that it is apt to encourage the pernicious habit of cramming.

J. deM.

HANDBOOK OF ANÆSTHETICS.—By J. S. Ross, M.B., Ch.B., F.R.C.S.E., and H. P. Fairlie, M.D. Fourth Edition. 1935. E. and S. Livingstone, Edinburgh. Pp. xv plus 299. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 7-14

THIS small book is written in a delightfully clear manner quite free from ambiguity. The essentials of the physiological aspect of anæsthetics in general are adequately discussed in the opening chapters. The next chapter is devoted to particularly clear instructions on the administration of anæsthetics and the care of the patient during the course of anæsthesia. The various anæsthetics are next dealt with in detail, their special physiological action being fully explained, and all the most modern methods and apparatus described.

Then there are three chapters on accidents and sequelæ of anæsthesia, and the posture of the patient, another short chapter on anæsthesia in labour and one on the choice of an anæsthetic. All the chapters are short but contain ample information. In the reviewer's opinion this brevity combined with remarkably clear style of expression is the great advantage of the book, for at the end of each chapter he felt he had absorbed its contents with no more effort than is required by careful reading.

At the end of the book are two chapters, one on local and the other on spinal anæsthesia.

It is a book that can be strongly recommended to the student for if he reads and absorbs the teaching it contains he will be competent to administer anæsthetics with very little extra instruction in the practical use of the various forms of apparatus.

THE TREATMENT OF FRACTURES.—By Dr. L. Böhler. Fourth English Edition. Translated from the Fourth Enlarged and Revised German Edition. By E. W. H. Groves, M.S., M.D., F.R.C.S. 1935. John Wright and Sons, Limited, Bristol. Pp. x plus 578 with 1,059 illustrations. Price, 42s.

ONCE again surgeons throughout the English-speaking countries must express their grateful thanks to Professor Hey Groves for his clear and excellent translation of Dr. Lorenz Böhler's book *The Treatment of Fractures*.

This work, which is a description of the methods dealing with the treatment of fractures in the Hospital for Accidents in Vienna, has already to a great extent been described in the previous three editions.

Dr. Böhler's earlier work was confined chiefly to the treatment of fractures of the limbs, but as his practice and fame increased, he was able to enlarge his hospital, and he now deals most skilfully in his clinic with every type of fracture and dislocation. His methods are widely known and highly commended by all surgeons, and his book has definitely taken its place as a classic in the treatment of fractures.

The fourth edition has increased in size, the chief additions being much longer chapters on the treatment of fractures of the spine, and of the os calcis. Fractures of the upper end of the femur also come in for special mention, and all the well-known methods of fixation are clearly described. Of the operative methods the author appears to favour that of the Smith-Petersen three flange pin.

Dr. Böhler is insistent that, in order to obtain the best results, perfect team work is essential, and x-rays must be unstintingly employed. He never uses general anæsthesia in reducing a fracture, local administration of novocaine, and occasionally regional anæsthesia being quite sufficient.

He does not believe in massage over the site of fracture but is enthusiastic in its use in neighbouring joints combined with movements.

He is scathing in his remarks about some practitioners who determine blood coagulability and basal metabolism, but allow joints to become stiff.

Dr. Böhler's own experience in treating fractures of the carpal scaphoid is interesting. He used to immobilize the wrist in plaster for four weeks, but results were not satisfactory. He now never takes off the plaster for at least six weeks when treating this condition as he has found that bony union is never complete before this date.

Not the least interesting parts of this book are the appendices, especially appendix D, which deals with fractures in relation to environment.

The book is a great achievement, and an excellent production. It should be added to the library of every hospital and surgeon.

H. E. M.

HEALTHY WEDDED LIFE: A MEDICAL GUIDE FOR WIVES.—By G. T. Wrench, M.D., B.S. (Lond.). Fourth Edition. 1935. J. and A. Churchill, Limited, London. Pp. ix plus 339. Price, 6s.

THIS book is written in simple language for the lay public and will probably be found of use by a certain number of people. At the same time it should be noted that a great deal of the subject-matter is only a discussion of ordinary common-sense principles of health which a large proportion of the public are quite capable of adopting without having to learn about them in a book.

The author is rather inclined to wander from his subject and long passages are devoted to discussions on exercise, food and the use of alcohol for example which have no special bearing on wedded life as distinct from the ordinary healthy life of an individual be he (or she) married or single.

It is a book that might be read with profit by the unthinking and ignorant, but we do not consider the person of average intelligence will learn much from its pages.

A TEXTBOOK OF BIOCHEMISTRY.—Edited by B. Harrow, Ph.D., and C. P. Shorwin, M.D., Sc.D., Dr.P.H., LL.D. 1935. W. B. Saunders Company, Philadelphia and London. Pp. 797. Illustrated. Price, 25s.

This new textbook is the outcome of the immense strides made in the subject of biochemistry in the last few years. No one at the present time is capable of writing intimately on all branches of the subject. The book containing thirty different chapters includes twenty odd different contributors each one a master in his own field. The field covered is extremely comprehensive and includes new developments which have only recently acquired an independent existence. The chapter on oxidation and reduction and the measurement of their potential is one which is undoubtedly going to be of considerable importance in the future since many or most biochemical phenomena consist essentially in this change.

The chapter on the biochemistry of bacteria, yeasts and moulds is interestingly written and is nowadays of considerable commercial importance apart from its scientific interest. The chapter on immuno-chemistry is well written by an authority on the subject and marks the co-operation of the biochemist and bacteriologist in the investigation of disease. An enumeration of all the chapters is impossible and it is unlikely that the whole book could be read critically by any one man. It should appeal to the biochemist, the biophysicist and the intelligent medical man with a bias in this direction although it should be pointed out that the latter will have to use his imagination and ingenuity as the book has not in general a medical trend. A good and not too large list of references is given at the end of each chapter. The writers have written their survey essentially to the point and made a critical and relevant selection of their material.

H. E. C. W.

OPHTHALMOLOGY IN GENERAL PRACTICE.—By O. G. Morgan. 1935. John Bale, Sons and Danielsson, Limited, London. Pp. 58. Illustrated. Price, 2s. 6d.

This little book of 58 pages is one of a series of 'Pocket Monographs on Practical Medicine'. It is written for the general practitioner in the hope of helping him to deal with the ocular conditions which he is liable to come across in private practice and those in which early and accurate diagnosis is of paramount importance to the eye.

With this end in view, the author points out the importance of a careful routine examination of the eyes and rightly lays stress that the focusing lens, the loupe and the binocular magnifier are of more value than the ophthalmoscope, as the great majority of the eye conditions for which the patients come for advice are in the front part of the eye, i.e., the lids, conjunctiva, cornea, iris and ciliary body. Short and very practical descriptions are given of the diseases affecting these parts of the eye-ball and their differential diagnosis.

The common diseases of the fundus that the practitioner is likely to come across in his daily routine are briefly described and can nowadays be so easily diagnosed by the electric ophthalmoscope if the practitioner will only take the trouble to use and master it.

The book is interesting but will hardly be sufficient for the general practitioner in India, a country in which

eye diseases are so common and comprise a large part of the cases that seek his advice.

E. O'G. K.

AIDS TO OPHTHALMOLOGY.—By N. Bishop Harman, M.A., M.B. (Cantab.), F.R.C.S. (Eng.), Hon. LL.D. (Man.). Eighth Edition. 1935. Baillière, Tindall and Cox, London. Pp. viii plus 242, with 124 illustrations. Price, 3s. 6d.

This excellent little book in 'The Students' Aid Series' has reached the eighth edition, the first having been written as far back as 1908. It comprises forty chapters condensed in a remarkably concise form and is mainly intended for the use of students before graduation.

The present edition has undergone a thorough revision to bring it up to date and much new matter has been added without adding appreciably to its size. A chapter on 'Standards of vision' has been included which will be found most useful in the examination of candidates for official and other appointments.

The author has very wisely not attempted to describe any of the rarer eye diseases. The book is written in a simple style, is well illustrated and eminently practical. It will be found most valuable not only to the student but to the general practitioner.

E. O'G. K.

ANATOMY. (THE THORAX.)—By C. R. Whittaker, F.R.C.S.E., F.R.S.E. Fourth Edition. Part V. (Catechism Series.) E. and S. Livingstone, Edinburgh. Pp. 59. Price, 1s. 6d. Postage, 2d.

This book of the catechism series deals with the thorax in the form of questions and answers. The mediastinum with its subdivisions has been carefully described and the contents of each subdivision have been clearly enumerated in a tabulated form. The heart has been fully dealt with in consideration of the importance of the organ, and its topography clearly indicated. The relations of the main organs and blood vessels have been put in a tabulated form. The new nomenclature has been chiefly adopted throughout. This small book will be extremely useful to students for quick revision of the subject during examination.

Abstracts from Reports

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR AND ORISSA FOR THE YEAR 1933. BY MAJOR S. L. MITRA, D.P.H., I.M.S., OFFG. DIRECTOR OF PUBLIC HEALTH, BIHAR AND ORISSA

Cholera statistics.—The death rate from cholera rose from 0.2 per mille in 1932 to 0.5 per mille in 1933. The districts of Cuttack and Balasore again reported the highest death rate from cholera, viz. 3.8 and 1.5, respectively. Amongst the towns Kendrapara (3.7), Jajpur (3.4) and Colgong (2.8) reported highest death rates.

Cholera in the province.—The total number of deaths from cholera in 1933 was 17,514 as compared with 9,348 in 1932. The districts in South Bihar and Chota Nagpur were comparatively free from cholera but the districts of North Bihar, specially Darbhanga, Champaran and Muzaffarpur had a mild epidemic of cholera at the close of the monsoon. The disease started early in an epidemic form in the district of Cuttack and Balasore and it was prevalent more or less

throughout the year. The civil surgeon of Cuttack with the help of the local bodies took prompt measures to control the epidemic. Twenty thousand people were inoculated against cholera and excellent results were obtained from the use of cholera phage in certain areas of the district. The epidemic of cholera in the district of Balasore, which caused 1,442 deaths, remained a special source of anxiety to the department for most of the year. Extra grants had to be made to the district board of Balasore for the appointment of epidemic doctors over and above the services of two doctors lent from the Government public health cadre. At Puri both the Snan and Rathjatra festivals passed off fairly successfully and the sanitary measures taken in the town under the supervision of the health officer proved quite satisfactory. No epidemic in the district followed the *mela*.

Cholera preventive measures.—With the growth of public health organizations in districts there is rapidly being created, in those districts which employ health officers, an efficient and well-trained staff to deal with outbreaks as soon as they occur. Twelve district boards now maintain health officers with a suitable subordinate health staff. There are fewer demands for extra epidemic doctors to combat cholera in these districts. But when the outbreak becomes serious and widespread and the district staff are unable to cope with the situation, officers are detailed from this department. Besides, temporary doctors are also employed by the Government to assist the local bodies in times of stress. Demands for epidemic doctors are usually numerous from the districts which have no permanent health organizations.

Stocks of disinfectants such as bleaching powder and permanganate of potash and also kaolin for use for the treatment of cholera cases are kept in reserve by the district boards. If required the civil surgeons requisition for these disinfectants and drugs from the Director of Public Health; the local bodies also get supplies of disinfectants from Government in cases of emergency. Government also maintain a large stock of cholera vaccine at the vaccine depot, Namkum. The superintendent, vaccine depot, is generally asked by telegram to despatch vaccine immediately wherever it is required. The number of doses of cholera vaccine issued has steadily increased and from 1923, 240,000, 656,300, 731,000, 666,510, 241,235 and 458,822 doses were supplied each year up till 1933. This preventive measure is getting more and more appreciated and now hardly any objection is raised to its use even in the remote villages. There are now indications to show that people of their own accord offer themselves for inoculations at the approach of the cholera season. Prophylactic inoculations against cholera are extensively carried out at all the important *melas* and this measure apparently proved effective in preventing the outbreak of a cholera epidemic after the Rathjatra festival.

Bacteriophage experiments.—In view of the encouraging results obtained with cholera phage in the two previous years in Purnea and Muzaffarpur districts of North Bihar, it was decided to continue the experiments in those two districts and to extend them to include the districts of Patna and Gaya in 1933. The arrangements of the last two years were accordingly repeated in these four districts, through the district boards concerned. Cholera phage was also used in dealing with the outbreaks of cholera in the districts of Puri, Cuttack and Bhagalpur.

Bihar witnessed another comparatively mild cholera year in 1933. The earlier months of the usual cholera season were comparatively free from epidemics. The intensity of the outbreaks was felt from the middle of July. Even after July the areas south of the Ganges escaped with fewer outbreaks. In the Northern district, the outbreaks were rather widespread except in Saran. Of the other five districts, the districts of Muzaffarpur and Purnea, where bacteriophage was

used, recorded comparatively few deaths, as will appear from the following table.

The following figures are from 1st January to 31st December, 1933, as furnished by the health officers:—

	Attacks	Deaths
Saran	306	127
Champan	810	518
Muzaffarpur ..	931	306
Darbhanga ..	2,042	1,097
Purnea	665	289
Bhagalpur	1,704	1,463

Purnea.—In Purnea district, out of a total of 665 cases, 289 deaths were recorded. Of 665 cases 333 were not treated with phage. Of these 333 cases, 214 died. Therefore the mortality among the cases who did not get cholera phage was 64.2 per cent. Of the remaining 332 cases who were treated with cholera phage, only 75 deaths were recorded, a mortality of 22.5 per cent. The average time taken to stop an outbreak completely after the use of phage was 3.26 days.

Muzaffarpur.—In the Muzaffarpur district out of a total of 931 cases, 306 died. Five hundred and eighty cases treated with phage had 79 deaths, a mortality of 13.6 per cent. The remaining 350 who had either no treatment or had been treated by doctors and *vaid*s recorded 263 deaths or 75.1 per cent.

It is significant that better results were obtained in Muzaffarpur district where a larger proportion of cases had received the phage treatment. Sixty-seven per cent of the outbreaks in Muzaffarpur district were completely stopped within two days and 77 per cent within five days of the use of phage. Only 11 per cent continued for more than five days. These long duration outbreaks were almost entirely confined to the out-of-the-way areas.

Patna.—In the Patna district there were fewer outbreaks of cholera. Of those treated with phage, 17 or 31.5 per cent died, and of the remaining cases treated otherwise in the villages, 39 or 53 per cent died. The duration of the outbreaks was two days in 76 per cent and five days in 92.3 per cent of the total outbreaks. Only in 7.6 per cent of the outbreaks did cases appear after seven days of application of cholera phage. The longest duration was 13 days in one scattered village, situated in an island of the Ganges.

Gaya.—In the Gaya district very few outbreaks were recorded. The progress of one outbreak was closely scrutinized by the Assistant Director of Public Health, South Bihar Circle. One night a cholera case arrived at Nawada railway station from Calcutta. He was offered phage, but the relatives refused it and took him to their village home at Gajra a few miles from Nawada and placed him under a doctor. He died the next day. Two cases soon appeared in the locality and were cured under bacteriophage treatment. The population was given phage. No further case was reported from the village.

The results obtained so far indicate that besides being cheap and easy of administration bacteriophage is better for the prevention and treatment of cholera than the usual methods. The use of bacteriophage has accordingly been extended, as far as possible, throughout the province.

ANNUAL REPORT OF THE MYSORE STATE DEPARTMENT OF HEALTH FOR THE YEAR ENDED 31ST DECEMBER, 1933

GENERAL

The state of public health in Mysore State was on the whole satisfactory in the year under report. The incidence of smallpox showed a tendency to rise towards the end of the year but the carrying on of

intensive vaccination campaigns in view of the forecasted increased prevalence of the disease helped largely to keep the disease under control. Plague was similarly controlled by the timely adoption of anti-disease measures such as evacuation, inoculation and disinfection. In the latter half of the year, an increased prevalence of influenza was reported in Chitaldrug district. The reaping of a good harvest of agricultural crops and a phenomenal fall in the prices of food grains were reported. The recorded rainfall during the year was 48.46 inches, the rainfall being above the average in all the districts.

The activities of the department having spread largely during recent years due to progress made from time to time in the advancement of health plans and procedures, a handbook has been published for the information of those interested in the State's health problems.

The agreement with the Rockefeller Foundation in respect of financing the budget of the Bureau of Health Education for two years terminated on 31st December, 1933, and Government have taken over the budget of the Bureau from 1st January, 1934.

At the Annual Dasara Exhibition, a Health and Sanitation Stall was organized as in previous years in order to popularize the anti-disease measures adopted by the department in controlling diseases like plague, smallpox, cholera, malaria and so on.

A popular health journal in Kanarese and English has been a long-felt want and the first issue of 'The Mysore Arogya' for the quarter ended 31st December, 1933, has been well received. It is proposed to improve this in the coming months.

Dr. W. C. Sweet continued to act as consultant in health to the Government of Mysore.

The cities of Bangalore, Mysore and Kolar Gold Field have had full-time health officers. So far as the districts are concerned, only Mysore and Shimoga districts have full-time health officers, the other districts having district medical officers as *ex-officio* sanitary officers. It is to be hoped that each district will soon have a health officer. Health work in the districts can be effective only when the entire staff of vaccinators and sanitary inspectors is transferred to the health department.

A spleen survey of 60 taluk headquarter towns was completed in the latter part of the year. Their rates were used to test the efficacy of a formula which has been worked out for the forecasting of malaria epidemics.

In order to devise measures for the control of malaria in the Anjanapur irrigated tract in the Shimoga district, a committee was constituted by Government. Anti-malaria work in the cities of Bangalore and Mysore was continued during the year and considerable reduction in the spleen rates in children under ten years of age has been observed. The reduction of spleen rates in Bangalore city from 23.2 in 1927 to 1.2 in 1933 indicates the value of the anti-malaria operations carried on in the preceding years.

Malaria relief work was started in the Irwin canal zone and was continued throughout the year.

The hookworm campaign was temporarily suspended during the year.

The control of guinea-worm disease in Chitaldrug district has been engaging the attention of the department and preliminary investigations in the biological control of the disease are being made.

Two sanitary inspectors trained in malaria work in the State were lent for about six weeks to the Director of Public Health, Bombay Presidency, to assist in the malaria survey work of the Poona suburban area.

Lanoline lymph enough for 585,810 cases was prepared at the vaccine institute, of which lymph enough for 302,942 cases was issued to stations inside the State and lymph enough for 3,655 cases to stations outside the State.

The public health institute examined 9,107 specimens in the bacteriological section and 705 in the chemical section and 707 articles in the medico-legal section.

One hundred and two cinema shows were given during the year in 45 different places to an audience of about a hundred thousand persons. The shows have become popular and requests for these are too many to be complied with, with the existing staff and a single motor van. There is therefore an urgent need for at least one additional unit with a few more films, if this type of propaganda work has to reach a larger rural population.

At the end of the year 1932, the number of piped water-supplies in the State were 30, serving a population of 691,991. Four existing water-supplies were improved during the year and their capacities enlarged, and the six new works installed serve an additional population of about twelve thousand.

Municipalities and village panchayats evince keen interest in the construction of bore-hole latrines and as many as 218 latrines were completed during the year.

The composting of night-soil in Mysore city is being continued.

An important feature of the rural health work in Mandya in the year under report was the control of plague and smallpox. A total of 5,208 anti-plague inoculations and 5,565 vaccinations was done.

The number of births reported in Mysore State was 117,920 during the year as compared with 115,627 in the previous year, and the computed birth rate was 17.99 as against 17.79 in the preceding year. The rates varied from 21.44 in Kolar district to 14.15 in Hassan district.

The number of deaths reported during the year was 106,009 as compared with 88,175 in the previous year and the computed death rate was 16.17 against 13.57 in the preceding year. The increase in the number of deaths was due to the reported increase of mortality under fevers. Some of the excess was also due to excess of mortality under dysentery and diarrhoea. The death rates varied from 26.66 in Chitaldrug district to 13.60 in Bangalore district.

The number of deaths recorded of infants under one year of age was 11,733 as compared with 11,026 in the previous year, and the computed infant mortality rate was 99.50 against 95.36 in the preceding year. The rates varied from 138.13 in Shimoga district to 58.28 in Mysore district.

The major health problems in Mysore State are the effective control of endemic diseases like malaria, plague and smallpox. Cholera, on the other hand, is not endemic in the State and assumes epidemic proportions once every four to six years.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1933. BY LIEUTENANT-COLONEL T. D. MURISON, D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, ASSAM

THE state of public health in the province during the year under review was not very satisfactory. Deaths under all heads of mortality, with the exception of smallpox, were larger during the year 1933. There was a severe cholera epidemic in the Surma Valley districts during the year. The largest increase in the number of deaths was from 'fevers' and this was followed by the increase under 'all other causes'.

A total of 161,054 deaths was recorded during the year, of which 5,508 were from cholera, 247 from smallpox, 103,890 from fever, 9,267 from dysentery and diarrhoea, 5,444 from respiratory diseases, 2,102 from injuries and 34,596 from 'all other causes'.

The total number of deaths from cholera reported during the year was 5,508, as compared with 4,971 in

is of great help in keeping down hookworm infection in the population and lessening the chances of its spread. In the present state of gross soil pollution in villages an untreated case of hookworm is a fruitful source for the dissemination of the infection in the community. During the year 218,143 treatments were given of which 10,722 treatments were given by the rural sanitation staff, 143,278 by the various medical institutions and the rest by other agencies.

Provision of latrines.—The bore-hole latrine is cheap and efficient and requires only minimum attention to keep it clean. The trench latrine is a modification of this for use as a public latrine in places where latrines are heavily used. The greater part of the time of the field staff was occupied in popularizing these latrines and in constructing them for local bodies and others. The designs for enclosures have to be modified in several instances to suit local conditions. During the year under report 1,572 latrine seats were constructed and 1,164 seats were either reconstructed or repaired. The extent of this work has been largest in Madura district where considerable sums of money have been spent during the last few years on this branch of work.

Public latrines alone cannot solve the problem of soil pollution. The section is now turning its attention to the task of bringing about the provision of a bore-hole latrine for each house. To encourage the construction of bore-hole latrines for private houses, the Madura district board has a scheme of giving squatting slabs at concession rates to individual house-owners. In other places, the district health officer's propaganda has been so successful that private contractors have undertaken as a commercial proposition to provide individuals with bore-hole latrines in their houses at an inclusive rate. This kind of enterprise should be encouraged.

The success of this campaign cannot be judged merely by the amount of the allotment or by the number of latrines put up by the unit, although these are of great importance. The real test of the success of the campaign must be judged by the readiness of the local authority to carry on this work after the unit has been withdrawn. This will be proof that the seed sown has germinated and is bearing fruit. This aspect of the campaign is being pressed on the section and the units so that they may so carry on the propaganda to ensure this desirable result.

Malaria

The scheme of free distribution of quinine which constitutes the main item of the campaign against malaria is financed entirely by the Government and functions in 13 out of the 26 districts of the province. Although a grant of Rs. 45,000 was made, equal in value to about 2,500 pounds of quinine, on account of the surplus stock available at the beginning of the year only Rs. 25,000 was utilized, equal in value to about 1,300 pounds of quinine. About a million and a half people came under the working of the scheme and of them 160,539 persons were treated during the year. Quinine is apparently becoming more and more popular with these people. This is due to increasing propaganda on the part of the district health staff and the slowly growing recognition on the part of the people in the malarious district of its usefulness in cutting short the course of the attack and minimizing the mortality due to the disease. In the three districts where the bulk of the quinine is distributed, the total death rate and the fever death rate have been showing a steady decline since the introduction of the scheme in 1928 up to 1932. There has been, however, an increase during the year under report which is probably due to local fluctuations and other extraneous causes.

As neither the local bodies nor the Government have the necessary finances to institute permanent anti-malarial campaigns in the endemic areas in the province, malarial surveys were carried out only in such areas where there was a reasonable prospect of

the actual work being undertaken as a result of the surveys.

Restricted anti-malarial measures, viz, treating with Paris green the breeding grounds in six villages, viz, Krishnadevipet, Chintapalli, Padwa, Pottanghi, Koraput and Jeypore, in the Vizagapatam Agency Tracts were continued during the year under the supervision of the agency surgeon, Koraput. The striking results at Krishnadevipet judged both by spleen rates and hospital figures recorded in the previous year show an even further improvement during the year under report. The spleen rate which varied from 10 per cent to 70 per cent in 1929 before the scheme was started now ranges from 6 per cent to 25 per cent in the seven villages on the banks of the Nagapuram and Krishnadevipet rivers which are the streams systematically treated with Paris green. The total annual cost for this campaign in this group of villages comes to about Rs. 2,500 for a population of over 7,500 and hence works out only at the rate of Re. 0-5-4 per head per annum.

Maternity and child welfare

In spite of unexpected set-backs there has been steady progress in this comparatively new branch of preventive medicine since the formation in 1931 of a separate section for maternity and child welfare in the Department of Public Health and the appointment of an Assistant Directress of Public Health (Maternity and Child Welfare). This progress is in a great measure due to the support of the Government who have in several Government orders stressed the importance of maternity and child welfare work, and have urged local bodies to institute and carry on suitable schemes with the advice and under the guidance of the Director of Public Health. Accordingly one of the first steps taken was to organize maternity and child welfare schemes on correct lines under their own administrative control.

Provision is being made in an increasing measure for ante-natal work. Home visiting, instruction to mothers and the supervision of the welfare of infants and children have been made regular features of the schemes. The work of the midwives and health visitors has been brought under systematic supervision.

Medical inspection of schools

The scheme for the medical inspection of schools has been held in abeyance owing to financial stringency.

Health propaganda

During the year under report new material was prepared and a revision of some of the old material was undertaken. The cinema now occupies an important place in health education and several portable cinema sets are now available with the health staff in the districts. Two cinema films were produced by the department during the year. One of them with the title 'Never say die' deals with leprosy. It is a four-reel film and has a good story which is much appreciated by the public. The other 'Better late than never' is on tuberculosis. The production of this four-reel film was financed by the Health Propaganda Board, Madras. There is a large demand from the districts for the supply of suitable films. Films depicting local conditions are of immense use for propaganda work.

A new set of coloured magic lantern slides on leprosy was also prepared during the year. The usual projection lantern worked with acetylene gas was found to be not only cumbersome for use by the health inspectors, but, owing to the constant care necessary to keep the gas generator and jets in good working order, it was also often neglected. An experiment was therefore made to alter this lantern in such a way that it could be worked with a baby petromax light. The experiment was a success and five lanterns were so altered for use by the health staff in the rural development area, Tiruvallur.

A pamphlet on food and popular dietaries was issued this year.

Eight lithographic coloured posters, seven on tuberculosis and one on cholera, were prepared and issued during the year.

Vaccination

There has again been a fall under primary and secondary vaccinations while the number of re-vaccinations has increased to a very considerable extent. The fall under primary and secondary vaccinations has been explained as due to the thoroughness of primary vaccination in previous years in some districts, whereas in a majority of districts it has been attributed to the widespread epidemic of smallpox which necessitated the vaccination staff devoting most of their time to re-vaccinations in and around infected areas and their consequent inability to visit the uninfected villages during the year for routine primary vaccination.

Industrial hygiene

A larger number of factories and cottage industries is springing up both in town and rural areas. Many local bodies have foreseen these developments and have made provision for them, but many more have failed to act and to set apart industrial areas. Consequently many mills have been built in unsuitable sites without consulting either the local health officer or the inspector of factories. In many of these places vested interests have exercised an undue influence over the local authorities and the collector and Government have had to take suitable action. The use of electric power for driving factories has introduced a new factor which will become increasingly important. Conditions which under the use of steam or oil rendered the proximity of a factory or mill obnoxious will under the new conditions not assume such importance and the question of locating factories under these conditions will be beset with new difficulties and a new outlook will be rendered necessary.

The recommendation of the Royal Commission on Labour for the appointment of an assistant director of public health for investigation of questions of industrial hygiene is under consideration of Government.

'DRUG ADDICTION IN INDIA AND ITS TREATMENT'

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to the article by Colonel Chopra in your March number on 'Drug addiction in India and its treatment', the value of lecithin in the treatment of opium addicts does not appear to have been assessed at its proper value. When attending the Ninth Congress of the Far Eastern Association of Tropical Medicine and Hygiene at Nanking, one of the things which struck me most was the great advance which had been made in the treatment of opium addicts. In China this is an urgent economic problem, and as far as one could gather from the authorities, they think that a very practical method of treatment has at last been arrived at. The work done in the Antiopium Municipal Hospital, Nanking, seems to show that, in the average case, soya-bean lecithin, when administered in daily doses of 60 to 90 grains, produces spontaneous gradual discontinuity in the use of opium by the addict. The use of lecithin may be discontinued a few days after a complete stoppage of opium. The addict is not subjected to any discomfort. He is allowed his usual opium either for smoking or eating and a comfortable spontaneous recovery takes place within a few weeks. It is not for me to give the details here as this has

been done by the originator of the method. This work has been carried out under the Chinese National Opium Suppression Commission and all information may be obtained either from the research workers themselves or from Dr. J. Heng Liu, Chairman of that Commission and President of the Ninth Congress. This successful campaign against the opium habit struck me so forcibly that on my return from China I suggested to the Surgeon-General with the Government of Madras that all medical officers under his control should be circularized officially with regard to this method of dealing with opium addicts in the same way that they are familiarized with other important curative and preventive methods. It is interesting to note that China has turned one of her great agricultural products, namely, the soya bean, to good account in counteracting the evil effects of another of her great agricultural products. The practical work of the Antiopium Hospital is founded on the experimental research of Dr. Wen-Chao Ma.

Yours, etc.,

R. E. WRIGHT, C.I.E.,
LIEUTENANT-COLONEL, I.M.S.

MADRAS.

13th June, 1935.

A PLEA FOR THE USE OF CONCENTRATED SALINE IN CHOLERA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR.—With reference to a letter published in the May issue of the *Indian Medical Gazette* on the subject of treatment of cholera by concentrated saline by Dr. Narayana Rao of King Institute, Guindy, I would like to say that the treatment suggested does not satisfy the main principles on which the efficient treatment of cholera is based, viz:—

(i) That the loss of fluid from the system should be replaced as early as possible.

(ii) That the toxins which are produced by the cholera vibrio and which are being absorbed from the intestinal tract should be destroyed. Fluid is necessary in this connection for dilution and elimination of these toxins.

(iii) That the acidosis and suppression of urine should be combated. Alkaline treatment is essential in this connection but the replacement of fluid is also very important as the latter raises the low blood pressure and helps in the re-establishment of urinary flow.

Experience at this institution teaches that the prognosis in cholera cases depends on the following main factors:—

(1) Above all early, timely and efficient treatment.

(2) Saline hypertonic injections. The quantity administered should be controlled by specific gravity of blood, blood pressure and rectal temperature readings. If this is done, the danger of complications such as œdema of lungs, severe reaction, and copious evacuations is minimized.

(3) Alkaline treatment to combat acidosis controlled by examination of urine.

This is the main line of treatment followed in this institution. During the recent epidemic season (1st March, 1935, to 29th May, 1935) 872 cases of cholera were admitted in this institution. Of these 169 died giving a mortality rate of 19.4 per cent.

This figure, considering the bad type of hospital case obtained in this institution, and the fact that the figures refer to the epidemic period, when mortality is always higher than in the rest of the year, is quite encouraging.

I am definitely of opinion that in the treatment of cholera, the administration of fluid plays almost as important a rôle as that of salts and alkalies and I regret I am unable to agree to the suggestion made

by Dr. Rao that salt may be the chief factor in reviving the circulation.

Yours, etc.,
N. C. KAPUR,
LIEUTENANT-COLONEL, I.M.S.
Superintendent.

CAMPBELL HOSPITAL,
CALCUTTA,
7th June, 1935.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL J. M. R. HENNESSY, Civil Surgeon, was appointed to officiate as Inspector-General, Civil Hospitals, Central Provinces, with effect from the afternoon of 7th May, 1935, *vice* Colonel N. M. Wilson, granted leave.

Lieutenant-Colonel B. Z. Shah, Superintendent, of Mahabaleshwar, is appointed to be on general duty at the Sassoon Hospital, Poona, in addition to his own duties, on the close of the Mahabaleshwar season, pending further orders.

Major R. S. Aspinall, an Agency Surgeon, on reversion to the Foreign and Political Department, is posted as Civil Surgeon, Ajmer, and Chief Medical Officer, Rajputana, with effect from the afternoon of the 18th April, 1935.

Major R. C. Wats is appointed as Officiating Director, Haffkine Institute, Bombay, *vice* Lieutenant-Colonel S. S. Sokhey, pending further orders.

Major D. P. Bhargava is appointed to officiate as Chief Medical Officer and Civil Surgeon, Delhi, with effect from the date on which he assumed charge of the post, *vice* Lieutenant-Colonel Paton, granted leave.

The services of Captain C. A. Bozman are placed at the disposal of the Government of Burma, for employment in the Public Health Department, with effect from the 13th March, 1935.

Captain H. S. Smithwick, Officiating Civil Surgeon, Sholapur, is deputed to be temporarily in charge of the Main Hospital in the Haj Camp, Karachi, opened for the treatment of persons injured in the earthquake at Quetta, pending further orders.

Captain J. E. Gray, Civil Surgeon, Nasik, is appointed to officiate as Civil Surgeon, Karachi, *vice* Lieutenant-Colonel M. J. Holgate, proceeding on leave, pending further orders.

LEAVE

Colonel N. M. Wilson, O.B.E., Inspector-General of Civil Hospitals, Central Provinces, was granted leave on average pay outside India for 4 months, with effect from the afternoon of the 7th May, 1935.

Colonel C. A. Gill, K.H.S., Inspector-General of Civil Hospitals, Burma, was granted leave, with effect from the 31st March, 1935, to 11th August, 1935, preparatory to retirement.

Brevet-Colonel H. H. Thorburn, C.I.E., an Agency Surgeon, is granted leave for 12 months, with effect from the afternoon of the 18th April, 1935.

Lieutenant-Colonel W. C. Paton, M.C., Chief Medical Officer and Civil Surgeon, Delhi, is granted leave for 5 months, with effect from the 17th May, 1935.

Lieutenant-Colonel S. S. Sokhey, Director, Haffkine Institute, Bombay, is granted leave ex-India for 4 months, with effect from the 15th June, 1935, or subsequent date of availing.

PROMOTIONS

Lieutenant-Colonel to be Colonel

C. E. Palmer. Dated 15th February, 1935.

Majors to be Lieutenant-Colonels

C. J. L. Patch. Dated 20th May, 1935.

S. L. Mitra. Dated 20th May, 1935.

Notes

SANOCRYSIN AND OLEO-SANOCRYSIN

We have received a booklet from the manufacturer of the above gold preparations. It contains brief but adequate descriptions of the nature of these drugs, the indications for their use, the methods of administration and their dosage.

These are followed by reprints of papers by medical men in charge of tuberculosis hospitals and sanatoriums giving their experience and advice regarding the use of these drugs. It will be found a useful booklet for anyone who intends to use these preparations or for those who have already used them but have not yet accumulated much experience. Although it is published by the makers of these two preparations it can be scarcely classed as an advertisement for the booklet contains only statements of fact backed by observation of medical men, no extravagant claims for the efficacy of this form of treatment being advanced.

Medical practitioners can obtain copies of this brochure on application to Messrs. H. R. Napp, Limited, 3 and 4, Clements Inn, London, England.

COW AND GATE MILK FOOD

Messrs. Cow and Gate Limited desire it to be known that Cow and Gate Milk Food is on sale in India in precisely the same form and packing in which it is prepared at the Somersetshire factories of the company.

Cow and Gate Milk Food is prepared under the very highest hygienic conditions and is immediately shipped to India for sale in its original containers. It is not shipped in bulk and repacked on arrival.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, any such action would constitute a breach of professional etiquette.

A PRELIMINARY REPORT ON AN EPIDEMIC DROPSY OUTBREAK IN PURULIA

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pharmacology

and

R. N. CHAUDHURI, M.B. (Cal.)

*Officiating Assistant Professor of Tropical Medicine
(From the School of Tropical Medicine, Calcutta)*

THE information collected by us indicates that the first outbreak of epidemic dropsy in Manbhum District occurred in 1913 and from this time up to 1926 no cases were reported. In 1927 a few cases were observed in the vicinity of Purulia but none in 1928 and 1929. In 1930 also there was a small outbreak in and around the town of Purulia and in 1932 and 1933 again some cases were reported with a few deaths. A widespread outbreak of an alarming character broke out in 1934 and started in the month of August in the town. The first reported death occurred in September in an affected family that came to Purulia for a change.

The intensity of the epidemic gradually increased and the disease spread into villages in the neighbourhood. It reached its height in November when it assumed a very widespread character. On information being received, one of us (R. N. Chaudhuri) was deputed to visit the place and report. Later, visits were paid by the senior author and Dr. Muir, and it was decided to send a small field unit to collect information.

Mr. Sen, the chairman of the Purulia Municipality, kindly made arrangements for us to take a census of the disease in the town by a house-to-house visit. This showed that over 2,000 individuals out of a population of 25,974 were affected during the current year. The deputy commissioner then started a survey of the whole district and, as far as our information goes, nearly all the villages towards the east and north of Purulia up to Raghunathpur police station and towards the west up to Joypur police station were found affected. An enquiry from 114 villages showed that about 5,000 individuals were suffering with the disease. The headmaster of the Manbhum Victoria Institution took a census and found that 35 per cent of the boys and staff of the school were suffering from it. The railway settlement at Purulia consisting of about 450 members was said to have 113 victims. The civil surgeon deputed a medical officer to tour the rural areas, and the information collected by him in 13 villages near Purulia is given below :—

Village incidence

Village	Population	No. affected	Village	Population	No. affected
Bhawanipur ..	700	85	Kodlah	300	50
Hutmena ..	600	50	Sodpur	100	25
Joynagar ..	200	40	Asjungorda	300	30
Lodurka ..	1,000	150	Chapba	500	10
Jojudi ..	250	40	Gangada	500	20
Chanchira ..	300	25	Charra	3,000	200
Ramdihi ..	300	100			

The mortality was heavy and some of these villages as well as Gorjoypur, Bhatbund, Kashi-pur, Gaurangdih, Talajora, Raghunathpur and Adra were visited by the field unit. A rapid survey was made and a large number of cases were seen in all the places except the last two where none could be found.

As on previous occasions in other places we found the disease was mostly prevalent among the upper and middle classes of the population. The disease was practically non-existent among the poor labouring classes, especially the Santals and Bauris. The few cases of the disease found among the latter class were in servants, who were having their meals at their masters' houses.

In order to study the family incidence we investigated twenty affected families in two villages.

There were 121 persons in these families and 74 were affected. The incidence of the disease in different families is given below :—

Family incidence

Serial number	No. in family	Number affected	Serial number	No. in family	Number affected
1	4	2	11	4	3
2	3	2	12	8	1
3	5	2	13	5	2
4	7	4	14	3	1
5	8	6	15	5	2
6	5	3	16	8	8
7	7	5	17	3	2
8	2	1	18	8	6
9	11	2	19	6	5
10	11	9	20	8	8

This table shows that twenty families consisting of 121 members had 74 victims during the time of our investigation. The severity of symptoms varied considerably in the members of the same family though the diet was the same.

Rice is the staple food of this district. In the case of the better classes, it is supplemented by vegetables, dāl, ghee, mustard oil and fish. In the case of the labouring classes the diet is mostly rice with salt and chillies, the other articles mentioned above being only used occasionally. Both classes use parboiled rice, which is as a rule husked at home. No milled rice is used by anyone, at least in the villages. Amongst the better class of people the rice necessary for the year's consumption is prepared from the paddy after the harvest and is stored in their houses, while the

labouring classes get payment in paddy from day to day and husk it into rice for immediate use. Another difference between the two classes is that while the better-off classes throw away the rice water, the poor labourers take it along with the rice. Further, the latter cook their food only once a day, at night; a part of it is kept overnight in cold water and is taken next morning and afternoon.

We collected samples of rice from different families in various localities. Many grains (50 to 80 per cent) in every sample even from unaffected houses showed central opacities. There was no notable difference in appearance between the old and new rice so far as opacity was concerned. Some samples of old rice were very friable and could be powdered with the fingers. We were told that a few years ago, when rice was sold very cheaply, rice merchants had purchased thousands of maunds of it and stored it in their godowns. Last year, owing to the scarcity of rain, the price went up and this rice was sold to the people. Samples of sun-dried or *atap* rice shown to us did not have such opacities and were not friable. Cultures were made from this diseased rice (opaque and friable) obtained from the affected houses. They were heavily infected with spore-bearing organisms of the 'vulgatus' group. Some strains of the organisms isolated agglutinated in quite high dilutions with sera of convalescent patients. This question is being studied in detail and the results will be published in due course.

We also collected samples of mustard oil from affected as well as unaffected houses as there is a strong belief among the local people that it is responsible for the disease; we had a few samples analysed. The specimens were mostly adulterated. Further investigations are being carried on to see if the oil contains any toxic substances.

In order further to study the epidemic in detail we decided to work in a small village by collecting data from the affected as well as unaffected families and to make clinical observations. We selected Gaurangdih, a village near Indrabil railway station, for this study. A field unit was stationed there to carry on epidemiological, clinical and bacteriological work along with relief work, and the results of this investigation will be published in detail later.

Clinical findings

Clinical examinations were carried out on a large number of the patients. In this paper we give the results of the analysis of the data of the first 66 patients. These patients were distributed among the following places—

Purulia—24, Bhatbund—10, Bhawanipur—9, Hutmura—10, Charra—13.

Sex. There were 35 male and 31 female patients. It is evident therefore that both the sexes are almost equally affected.

Age. There was no case under the age of four years.

Age incidence

Age group	Incidence	Age group	Incidence
4 to 10	17	41 to 50	6
11 „ 20	15	51 „ 60	2
21 „ 30	11	61 „ 70	1
31 „ 40	12	71 „ 80	2

In a previous paper Chopra and Basu (1930) showed that nearly all the patients in a series of 19 were under 30 years of age. This table shows that only 11 out of 66 patients were over 40 years, and that the disease is rare in the very young and the very old.

Symptomatology

Bowels.—Prenomitory diarrhoea was a common complaint. In this series 43 cases (65 per cent) had suffered from diarrhoea, especially at the onset. Diarrhoea preceded oedema in 34 cases, while oedema preceded diarrhoea in 4 cases only. The sequence could not be ascertained in the other four cases. The severity of the diarrhoea was variable, the majority had simple diarrhoea of a mild type, but in some patients it was so severe as to simulate cholera. We saw one girl who was actually treated for cholera with intravenous saline injections; later, with the stoppage of diarrhoea, her legs became swollen and she showed a typical picture of epidemic dropsy.

A large number of stools were examined; their colour was variable, yellow, green or white; mucus was seen in the stools of a certain number of patients and sometimes it was associated with blood, thus simulating the stools in dysentery. The remaining patients were constipated and did not give a history of early diarrhoea. Borborygmi, sometimes associated with griping pains, were common even in patients who had no diarrhoea.

Palpitation was a common symptom and varied in severity; 36 (54.5 per cent) complained of it at some time or other. The heart was examined in all cases. Enlargement of varying degree was noticed in 14 (21 per cent), the first sound in the mitral area was clear or accentuated in 52 (79 per cent), while it was replaced by a soft bruit in 11 (17 per cent); in 3 (4.5 per cent) cases it was muffled. The second sound in the pulmonary area was normal in 52 cases, accentuated in 13 (20 per cent) and reduplicated in one. A soft systolic bruit in the pulmonary area was present in 5 (7.5 per cent) cases, and 3 of these had a similar bruit in the mitral area. The aortic second sound was accentuated in 3 cases. Signs and symptoms of grave cardiac failure with dilated heart, venous engorgement, dyspnoea and embryonic rhythm were noticed in 3 cases.

Breathlessness on exertion was another important feature and 26 patients (39.3 per cent) complained of it. The rate of respiration was counted in all cases. It was under 20 per minute in 2 cases, between 21 and 25 in 31, between 26

and 30 in 11, between 31 and 35 in 12, between 36 and 40 in 5 and between 41 and 45 in one; it was not recorded in 4 cases. This shows that the majority of patients had an increased rate of respiration. Thirty-six patients complained of cough and in some of them it was of a very distressing character. In most instances it was dry and irritating, streaks of blood were noticed in the sputum in a few cases. Out of these 36 patients 15 had adventitious sounds (râles and rhonchi) in the lungs especially at the bases, 3 of them were, however, subjects of chronic cough and possibly of bronchitis.

The pulse rate was variable depending on age, degree of cardiac affection and severity of the individual case. The majority of the patients (66.6 per cent) had tachycardia with a pulse rate varying from 90 to 140 per minute or more. The volume and tension were variable.

The blood pressure was measured in 57 cases and in many it was found to be raised.

Blood pressure records

Males

Age	Systolic	Diastolic	Age	Systolic	Diastolic
5	80	50	30	125	85
8	113	78	30	145	85
9	105	75	30	102	66
10	112	60	32	142	90
11	106	80	40	140	68
11	108	65	40	115	75
12	108	70	42	148	90
12	124	54	46	130	72
16	140	90	50	176	100
19	128	90	50	130	76
22	115	65	62	205	105
24	154	82	72	132	65
24	140	75	73	150	76
24	153	88			

Females

Age	Systolic	Diastolic	Age	Systolic	Diastolic
4	106	72	15	125	80
5	88	55	16	130	86
5	125	72	16	128	80
6	103	69	18	132	90
6	100	62	20	134	88
7	102	68	24	110	72
8	122	70	25	108	66
8	116	64	28	118	66
8	128	62	30	132	80
10	100	62	30	125	85
10	122	78	32	124	76
11	120	74	32	112	72
15	118	72	35	124	84

If '100 plus age' be considered as the physiological maximum of systolic blood pressure, it is evident from this table that the blood pressure of 16 males and 14 females in this series was abnormally raised, also that the pulse pressure is raised in 20 cases.

The liver.—This organ was definitely enlarged in 23 patients. Although it was hard to decide, at least in some, whether the enlargement was of recent origin or not, the liver was somewhat tender in many cases.

Cutaneous manifestations.—Edema was a constant sign. It was actually present during our examination in 50 cases, and the remainder had had it previously. As a rule it followed diarrhoea. The swelling seemed to make its first appearance on the front part of the leg, about the lower third of the tibia. It is usually of a plastic nature, so that when the thumb is pressed on it, a small depression is left which disappears in half a minute. It is often at this stage that cases are first diagnosed as epidemic dropsy. In the majority of cases œdema was confined to the limb below the knee, but the thighs, sacral regions and hands showed œdema in some patients. None had œdema of the trunk or face, nor gave a history of it in these sites. A rash was observed in 14 patients, the legs and thighs being the commonest sites for this. It was usually macular or erythematous in type, while peculiar mottling was commonly seen on the inner aspect of thighs. The angiomatous nodules, i.e., sarcoids, were seen in 4 cases only. Increase of pigment in the skin, especially on the forehead and cheeks, was a special feature in a large number of cases. It was most marked when the disease had persisted for a few weeks and when the acute symptoms had more or less subsided.

Fever.—Many patients suffered from fever specially in the acute stage. We recorded the temperature of 57 patients during our examination. Altogether 20 had a temperature over 99°F. and some had a remittent type of fever.

Nervous symptoms.—The knee jerks were tested in all cases. They were normal in 57, increased in 5, decreased in 3 and lost in 1 case only. Three patients with increased knee jerks had patellar clonus also. There was no definite evidence of neuritis, although tenderness of the calf muscles was present in a few cases. Aching of the body and extremities and generalized burning sensation were common subjective nervous symptoms. Many suffered from general asthenia and insomnia. The eyes were examined in every case. The pupils were equal and reacted to light and accommodation; the tension appeared to be normal on palpation, the vision was however hazy in eight patients as a result of the disease, while three complained of seeing coloured haloes around the light at night.

Abortion.—Reports obtained in many villages pointed to the fact that every pregnant woman had aborted or miscarried as a result of the disease, no living child was born for several months in some of the villages, abortions occurring mostly between the fourth to eighth months of pregnancy. There were no special symptoms noted in these cases, labour pains started prematurely and the dead fœtus was expelled. Excepting in one case reported to us there was no excessive hæmorrhage in any case. In some cases hæmorrhagic blisters were seen on the body of the dead fœtus.

Treatment.—In Purulia we had an excellent opportunity of trying the treatment of epidemic dropsy suggested by the senior author and which is that adopted in the Carmichael Hospital for Tropical Diseases. We are grateful to the local authorities for the facilities they gave to us. The Indian Research Fund Association and chairman of the district board kindly gave us grants towards the maintenance of the field work and the civil surgeon of Purulia kindly supplied us the necessary medicines free of charge. He also had this treatment carried out by the district board dispensaries and at special centres opened to combat the epidemic. The principal factors in the treatment that have proved so efficacious in our hands are :—(1) Rice-free diet, (2) rest, (3) initial purgative and (4) administration of tincture ephedra (20 to 30 minims) with 10 grains of calcium lactate two or three times a day. Strychnine and iron were also given in a few selected cases. Ephedrine acts in very much the same way as adrenalin, its action being not so powerful but more prolonged. It counteracts the capillary crisis that occurs in this disease and hastens the process of circulation. Further, large quantities of pseudoephedrine contained in the Indian ephedras have a marked stimulant action on the myocardium. The surgeon to the Purulia Sadar Hospital and the chairman of the municipality visited various centres in the rural areas along with the assistant director of public health and reported to us the beneficial results of treatment with tincture of ephedra and calcium lactate. Advanced cases with organic cardiac changes require subsidiary treatment before the full effect of tincture of ephedra can be obtained. In such cases venesection, glucose and diffusible cardiac stimulants were recommended along with very prolonged rest in bed. We also observed that there was no improvement in those cases where rice as an article of diet was not completely stopped. We have seen several instances of patients who, while under treatment, took rice and had a relapse of the signs and symptoms.

Summary

An historical review of the incidence of the disease shows that the epidemic did not occur every year. Although small outbreaks occurred in previous years, 1934 was the only year with a big epidemic and high mortality rate.

Selection.—Although all the members of a family were on the same diet, the severity of symptoms varied enormously in those affected while some members remained quite free from the disease. Children under four years of age in this series entirely escaped, probably because they usually consume small quantities of rice. The poor labouring class living only on freshly-husked rice did not contract the disease. Servants from this class, having meals at their masters' houses, became affected with the disease

but they did not communicate it to other members of their families.

Stored parboiled rice and mustard oil are two suspected articles of diet in the diseased families. Patients recover quickly after the stoppage of rice; relapses almost invariably occur if rice is resumed early.

Gram-positive organisms of the 'vulgatus' group were isolated from the stools of patients, some strains agglutinating with the sera from convalescent patients. The strain isolated in Calcutta agglutinated with the sera collected at Purulia. This important finding shows the possibility of preparing anti-toxic sera for curative purposes.

The symptomatology has been described. The increased pigmentation of the skin is an interesting new observation.

Treatment with tincture of ephedra and calcium lactate proved effective.

Appendix

Outbreak of epidemic dropsy in the engineering camp at Purulia.

The senior students of the Bengal Engineering College have been sent to Purulia for survey training every winter for the past fifty years. Unfortunately the camp during last winter had to be dissolved owing to an outbreak of epidemic dropsy among the students.

A widespread epidemic of an alarming character was prevalent in Purulia and its suburbs last year and it was at its worst during the month of November when the camp was actually started. A batch of sixty-three students arrived on the 5th November, 1934, and encamped within about a mile of the town. Tents were placed according to the following plan.

There were four tents (1, 2, 3 and 4), placed at a distance of about fifteen feet apart and three adjacent ones to serve as kitchens (A, B and C). The Mohammedan students who were only seven in number occupied tent no. 1 with its adjacent kitchen A, while the Hindus numbering fifty-five used the remainder of the tents and kitchens. There was one Anglo-Indian student who messed with the Mohammedans. The water supply for both Hindus and Mohammedans was from the same tank. There was no special latrine arrangement. Provisions and food were purchased locally from the Purulia market, the Hindus bought rice from a local Hindu *bania* and the Mohammedans bought theirs from a Mohammedan dealer. Both sections used mustard oil prepared in the local mills and their supply of ghee was brought from Calcutta. With regard to other articles of diet, the Mohammedans had a mixed

diet, while the Hindus lived more or less on strict vegetarian diet.

Owing to the prevalence of cholera most of the students were inoculated against the disease; a small number refused. The camp carried on without incident till 7th December, when ten Hindu students complained of diarrhoea; frightened by this, most of the remaining students were inoculated. On the 13th of December more of the Hindu students had looseness of the bowels and the assistant surgeon from the local civil hospital was called in. He found that thirty-five Hindu students had gastro-enteritis and about twenty had oedema of the legs. He visited the camp next day and saw altogether twenty-seven students with diarrhoea and oedema, nineteen with diarrhoea only and four with oedema only.

The menial staff were twenty in number, of whom fifteen were Hindus and six were Mohammedans. Seven of the former were affected while none of the latter had any symptoms. One student and two menials showed serious symptoms.

This created a panic and the camp was dissolved forthwith. The students were given leave and advised to go to their respective homes and one was admitted to the Howrah General Hospital for treatment.

We visited the college after the students had returned, and found that practically all of them were apparently cured. As far as our enquiry goes, there was no subsequent outbreak in the hostel at the college among the other students nor in the families of the victims.

We collected samples of rice and mustard oil used by the affected students. The rice was of the 'Ramsal' type, the grains were of various colours indicating admixture of different kinds. The water test showed opacities in over eighty per cent of the grains and on culture there was a heavy growth of bacilli of the 'vulgatus' group. The mustard oil was analysed in the Bengal Public Health Laboratory and found to be adulterated. We are thankful to Mr. McDonald, the Principal of the Bengal Engineering College, for the facilities given to us.

Summary

Eighty-three per cent of Hindu students in the camp were affected, while all the Mohammedans escaped. The disease could not be contagious nor water-borne as the students of both classes mixed freely with each other and had the same water supply. The diet was the principal factor of difference between the two classes, provisions being supplied by different contractors. The rice used by the affected students was heavily infected. The outbreak was explosive in character, and at the outset the disease was characterized by diarrhoea in almost every case. There was no spread of the disease to the students' families nor in the hostel of the Bengal Engineering College to which they returned after the epidemic.

THE OCULAR COMPLICATIONS OF EPIDEMIC DROPSY

By E. O'G. KIRWAN, F.R.C.S.I.

LIEUTENANT-COLONEL, I.M.S.

Professor of Ophthalmology, Medical College, Calcutta

THE main ocular complication of epidemic dropsy is glaucoma of the primary non-inflammatory type, and the eye remains quite white even in cases in which the tension is extremely high. Formerly it was thought that the increased intraocular tension was a late manifestation of the general disease, but in the outbreaks in 1932, 1933, 1934 and 1935 many cases of this type of glaucoma were seen with slight or no other general signs of the disease. In the latter category, some gave a history of having contracted the disease in a previous epidemic, but, on the other hand, a number gave a negative history of any other signs or symptoms of the disease, so that in some cases the toxins showed a special predilection for the intraocular capillary endothelium, while, in the majority of cases, this endothelium was involved with the general endothelial system of the body.

Glaucoma is more often seen in persons between the ages of 20 and 35, but cases of high intraocular tension also occur in Indian boys and girls from 8 to 15 years of age.

The early symptoms of glaucoma to be noticed by the patient are rainbow colours, haloes around lights, and gradual diminution of vision. These haloes are at first transient but as the disease becomes more marked they become permanent. Both eyes are nearly always affected at the same time, although some patients give a history of one eye being affected first. The disease is not accompanied by pain although occasionally there is a sensation of discomfort or heaviness in the eyes. Nausea and vomiting are absent. In all cases the conjunctiva and sclera are not affected except for the turgescence of the anterior ciliary veins which stand out prominently, and in those cases in which congestion of the conjunctiva was observed it was always explained

by the previous instillation of eserine. The corneas may be normal or they may have a steamy or ground-glass appearance depending as a rule upon the amount of increased intra-ocular tension, but in all cases examination with the corneal microscope shows evidence of corneal œdema. The rainbow rings—which are due to œdema of the cornea are always a marked symptom of the disease and their presence is an important point in distinguishing the glaucoma of epidemic dropsy from simple primary glaucoma, as in the latter variety the rainbow haloes are not always present. As a result of seeing these colours, patients suffering from this type of glaucoma come for treatment much earlier than those suffering from the ordinary chronic simple variety.

The anterior chamber is never shallow as in other types of glaucoma; it is either normal or deeper than normal and there is never any pushing forward of the lens and iris. It is of great interest to note that this variety of glaucoma is of the anterior segment type, in contradistinction to the posterior segment type in which the anterior chamber is shallow. Swelling of the vitreous body which usually plays a predominant part in the pathogenesis of glaucoma is absent and therefore swelling of this body is not necessarily an essential factor in the causation of glaucoma. The increased intra-ocular pressure is due to the dilatation of the capillaries of the whole uveal tract, followed by an increased permeability of the endothelial walls which leads to an increased output of intraocular fluid in the anterior segment of the eye.

In the photomicrographs of the filtration angle it will be seen that the canal of Schlemm and the tissues in the immediate vicinity do not show any abnormalities, either in cellularity or increased fibrosis. The epithelium of the ciliary processes also does not show any change. Marked dilatation of the vessels is seen in the subepithelial connective tissue of these processes. There is also an enormous dilatation of the capillaries of the choroid. There is no evidence of any inflammatory process to be found in the whole of the uveal tract.

Recently I have been 'tapping' the anterior chamber and have been able to take off 0.25 c.cm. of aqueous humour. This fluid has been examined for me at the School of Tropical Medicine, Calcutta, and in a number of cases the presence of a toxin containing an 'H' substance resembling histamine in its action has been proved to be present. At the same time, controls with normal aqueous humour did not show the presence of this substance. This is a great advance in our knowledge of the ætiology of epidemic dropsy and as the epithelial cells of the ciliary body do not show any damage microscopically, this toxin is probably produced from specific micro-organisms in the alimentary canal.

Examination of the blood serum of patients suffering from epidemic dropsy shows that the total proteins have diminished and this diminution is due to a considerable decrease in the albumin content. As the protein content of the serum is responsible for the physical state of the blood, so these changes must necessarily have a great influence on the various physical and chemical properties of the serum. Examination of the aqueous in epidemic dropsy glaucoma shows that the percentage of albumin is greatly increased while the globulin remains the same; the normal ratio of albumin to globulin is 0.45 to 1.0 whereas in the aqueous of epidemic dropsy glaucoma the albumin is more than the globulin in the ratio of 2.5 of albumin to 1.0 of globulin. Examination of the crystalloids in the aqueous humour shows no deviation from the normal.

The pupil is normal in appearance and reacts well to light and in accommodation. Examination with the corneal microscope shows no evidence of inflammation in the aqueous nor the iris. Pathologically we know that the vessels in the iris are dilated, but, owing to the heavy pigmentation of the iris in the Bengali, the vessels in the living eye cannot be seen. The ciliary body, like the iris, is not involved except that weakness of accommodation is nearly always present. The media and lenses are normal. Even in advanced or absolute glaucoma of this type lens opacities are never observed. The fundus cannot always be seen clearly owing to corneal œdema, but in most cases glaucomatous cupping is not present except in long-standing cases of three or four months' duration. Cupping and atrophy of the disc become more marked according to the duration of the disease. It is of interest to watch the formation of the glaucomatous cup; this is gradually formed by enlargement of the physiological one. The fundi were examined in a large number of cases, both before operation and also after operation when the intraocular tension had become normal but no gross changes were found. The veins were either normal in size or showed some engorgement and they appeared much darker than normal. Retinal hæmorrhages do occur but are extremely uncommon, and I have never seen any new formation of blood vessels as is seen in other parts of the body. Retinal exudations do not occur.

The outstanding phenomenon of this variety of glaucoma is the extremely high tension. It is rarely below 50 mm. of mercury (Schiotz); tensions of 70 to 100 mm. are quite common, and I have seen some cases in which the intra-ocular tension was over 100 mm. The tension as a rule remains high constantly but cases occur in which it varies tremendously, even dropping to normal for a short time. Both eyes are affected and I have seen a few cases in which one eye was affected first, but invariably the other was involved a few weeks later.

The tension is usually about the same in both eyes. The optic nerves seem to be able to resist the high tension for a number of weeks before any evidence of atrophy is found in the visual fields, but unless the tension is relieved optic atrophy of some degree invariably results, at times progressing to complete blindness. Cases are seen in which the glaucoma disappears spontaneously after the general disease has disappeared, leaving defects in the visual fields dependent on the duration of the increased intraocular tension. I shall not discuss in detail the defects in the visual fields as they are much the same as those in chronic primary glaucoma. In early cases there is a depression of the peripheral fields starting in the nasal quadrants. In later stages the fields show a concentric depression. The colour fields react in the same way as the fields for white, and shrink as the fields become depressed. Examination of the central field shows a pericæcal depression and the scotoma is continuous with the blind spot to a varying extent.

Some observers are of the opinion that glaucoma does not occur in cases in which there is profuse diarrhœa, but this is not my experience, and I have seen many cases in which high intraocular tension has been accompanied by diarrhœa. Purgation produced by the administration of salines has no effect in lowering intraocular tension in this type of glaucoma.

Treatment.—In the treatment of glaucoma, the important thing is to eliminate rice completely from the diet, and to wash out the alimentary canal by the administration of purgatives and large amounts of fluid, in the hope that the offending organisms and their toxins may be eliminated from the body. In very

any length of time. The dietetic and medicinal treatments of this type of glaucoma are most unsatisfactory. Some patients get well without any therapy, but invariably a damaged visual field results depending upon the severity and duration of the disease. Purgatives and diuretics are of little use even to reduce the tension to a lower level. Miotics, such as pilocarpine and eserine, which are still commonly used by many doctors are absolutely useless, so much so that they have now been abandoned even as a temporary measure in the treatment of this variety of glaucoma in the Eye Infirmary, Medical College, Calcutta. I cannot impress too much upon medical men the importance of never prescribing eserine drops. Eserine is a very potent drug causing pain in the eye and symptoms of irritation. It has the added disadvantage of causing hyperæmia of the conjunctiva thus making operative treatment much more difficult.

As long as the visual fields show no defect there is no necessity for carrying out an immediate operation. It is possible that the general disease, and with it the glaucoma, will be cured before the optic nerves become permanently damaged by the increased intraocular tension. The patient should be kept under observation and should refrain from eating rice, but, as soon as the defects in the visual fields become evident, operation should not be delayed.

Case 1.—Hindu male, age 24 years.

Previous history.—No history of previous attack of epidemic dropsy.

Present history.—Contracted epidemic dropsy three months ago which was characterized by swelling of the feet. History of seeing rainbow haloes around lights for about two months.

CHART I
Early case

White object 33 + 1000

early cases, the most practical therapeutic measure is to get the patient away from the endemic area, as it is difficult for the average Indian patient to refrain from eating rice for

Right eye.—Cornea—clear, anterior chamber—deep, pupil—active, tension—65 mm. (MacLean), vision—6/9.

Left eye.—Cornea—clear, anterior chamber—deep, pupil—active, tension—60 mm. (MacLean), vision—6/9 (see chart I).

Case II.—History of an attack of epidemic dropsy since 7th February, 1934. Characterized by swelling of feet, diarrhoea, pains in arms, palpitation of heart. Complained of occasional haziness of vision in both eyes since the attack. Haloes round light.

Patient used to take rice.

Right eye.—Cornea—clear; A. C.—deep; pupil—active; tension—56 mm.; white object ३३३ + १००० and vision 6/6.

Left eye.—Same as the right eye.

One would think that this type of glaucoma, being of all known varieties a primary glaucoma, a temporarizing operation could be done, as the patient will get well spontaneously, when the cause is removed, and that it is only necessary to keep the tension down by repeated anterior sclerectomies until this end is achieved. In practice, this is not sufficient, as it takes a

CHART II

Case III.—Hindu female, 24 years old.

History of an attack of epidemic dropsy for last one month, characterized by swelling of feet, palpitation of heart and seeing haloes round light.

Present history.—Patient contracted the disease in Jessore.

Family history.—Other members of the family have been suffering from the same disease.

Right eye.—Cornea—clear; A. C.—deep; pupil—active; tension—67 mm.; white object ३३३ + १००० and vision 6/6.

Left eye.—Same as the right eye.

Both eyes.—Trophined B. H. I. done; tension—normal after operation.

considerable time to get the disease under control in spite of the withdrawal of rice from the diet and the use of eliminative treatment. I have recently carried out anterior sclerectomies to tap the aqueous humour for examination, but in practically all cases the tension goes up again in the course of a few days. By far the most successful method is the Elliot operation with a 1½ mm. trephine. During the operation, as may be expected, the aqueous escapes under great pressure. A small peripheral

Fig. 4

iridectomy is done. I have never seen intra-ocular hæmorrhage at the time of operation, even when operating on eyes with extremely high tensions. The results of trephining are excellent and the tension seldom rises again once the decompression is carried out. In the course of time, when the general disease is cured, the trephine hole closes. The operation is simple and excellent in its results, and in the large number of trepanations that I have done in this type of glaucoma I have been fortunate enough never to lose an eye.

Discussion.—It is of interest to note that the optic atrophy is caused by the increased intra-ocular pressure alone and cannot be attributed to the toxins that cause epidemic dropsy. Once the increased intraocular tension is relieved by operation and the tension of the eye remains normal, optic atrophy ceases to progress. In a number of cases I have observed the fields carefully for a considerable time after operation, in a few patients up to a maximum period of 6 years, and invariably the field has remained the same or has slightly improved after operative treatment.

This problem in the elucidation of the ætiology of epidemic dropsy is of extreme importance, not only in the treatment of glaucoma associated with this disease, but in the elucidation of all glaucomas. It need hardly be pointed out how very common glaucoma is in India and its responsibility for a large amount of the partial blindness and blindness that is to be found in every town of this vast country. We are still, in the words of Lieut.-Colonel R. L. Wright, 'in almost complete ignorance of the essential origins of such local changes in the eye, although it is hardly likely that we can dissociate them from the generalized phenomena of a similar nature throughout the body due to the same original causes'. If we can find out the organism and its toxin that is the cause of epidemic dropsy, we have advanced a considerable distance in the elucidation of the whole glaucoma problem, and will have conferred a benefit, not on Bengal and India alone, but on the world in general, as in all countries primary glaucoma is extremely common. I have no doubt that in a short time the ætiology of the disease will be definitely cleared up, and so one can look forward to the day when a great part of the problem of glaucoma will be solved by therapeutic methods or methods of prevention.

The case notes and the charts of the visual fields of three cases are given; these maps show the visual fields of early, advanced, and late glaucoma associated with epidemic dropsy.

My thanks are due to Lieut.-Colonel R. N. Chopra, I.M.S., Capt. C. L. Pasricha, I.M.S., and the staff of the School of Tropical Medicine, Calcutta, for their assistance in the examination of the aqueous humour, and to Dr. N. De, Professor of Pathology, Medical College, Calcutta, for making the photomicrographs.

PATHOLOGY OF EPIDEMIC DROPSY

By M. N. DE

and

K. D. CHATTERJEE

(From the Department of Pathology, Medical College, Calcutta)

AMONGST the protean manifestations of the disease which we commonly call epidemic dropsy, the changes in the skin constitute one of the most puzzling features in its pathology. Although, in the present unsatisfactory state of our knowledge regarding the true nature of the malady, we do not know the causes that bring about these changes, yet the morbid anatomy and the histopathological changes in the skin have been more or less accurately studied.

Clinical lesions: The skin.—The skin may be affected in epidemic dropsy in a variety of ways. In some cases, particularly in the early acute stage of the illness, the lesions may be limited entirely to the superficial layers. In such cases, the skin shows a very characteristic blotchy erythema with a somewhat vivid purplish-red coloration as if there is an acute dermatitis. This may be found not only in the dependent parts of the body but also in other areas where the question of hyperæmia due to gravity does not arise. There may not be any gross swelling and œdema nor any pain nor tenderness. Such a picture is often associated with a low intermittent type of pyrexia which yields remarkably to injections of adrenalin. This erythema is due to the dilatation of the superficial vessels of the skin, as slight pressure will often remove it although it returns almost immediately the pressure is removed. A very curious phenomenon is sometimes met with in such cases. A severe uncomfortable aching pain is felt underneath the finger and toe nails. This becomes, at times, so distressing that patients feel relief when they apply a tight pressure bandage over them. After some time, which may extend over some weeks, varying degrees of swelling and

DESCRIPTION OF PLATE IV.

Fig. 1.—Photomicrograph of the filtration angle of the eye from a case of epidemic dropsy.

The channels of absorption (canal of Schlemm and tissues around) do not show any abnormalities either in cellularity or increased fibrosis.

Figs. 2 and 3 show different parts of the ciliary body. The epithelium of the ciliary processes do not show any change. Marked vascular dilatation is present in the sub-epithelial connective tissues. There is no evidence of any inflammatory processes.

Fig. 4.—Photomicrograph of the choroid from a case of epidemic dropsy showing enormous dilatation of the capillaries. Such a vascular change in the choroid coat often gives an impression of hæmorrhage although actual extravasation of blood in the tissues does not take place. The wide gap between the vascular and pigmented layer has been apparently caused during the preparation of the specimen.

œdema characteristic of the disease appears, particularly in the lower extremities.

When a piece of skin thus affected is excised and subjected to a microscopic examination, all the changes are found to be confined to the papillary blood vessels which are dilated and engorged. There is no appreciable involvement of the deeper subcutaneous adipose tissue. No inflammatory reaction is noticed in any part of the skin. This change may disappear as the patient improves and the skin surface may almost completely regain its normal colour, leaving behind some degree of pigmentation. In some cases the degree and intensity of such pigmentation is so marked that a fair-skinned person often looks quite dark.

In other cases, the disease starts with marked swelling and œdema of the lower extremities which may definitely pit on pressure. This appearance is very characteristic. The swelling is tense, somewhat shiny, and usually there is a deep subcuticular reddish flush. Some pain and tenderness may be elicited specially on deep pressure, and the parts feel warmer. In very severe cases, ecchymotic patches with a deep chocolate colour may be found in different parts of the body, specially in those areas where there is much fatty tissue, as for example in the buttocks, and thighs.

The histopathology of these subcutaneous manifestations have been adequately studied and reported by Acton and Chopra (1927), Shanks and De (1931), and De (1933). The most characteristic changes are seen in the blood vessels of the subcutaneous fatty tissue (plate V, figures 1 and 2) which are almost transformed into a capillary angioma. This vascular dilatation, though present in the superficial layers of the skin, is not very striking. The ecchymotic patches mentioned above are found to consist entirely of such telangiectasis instead of actual hæmorrhage into the tissues.

Development of fleshy dark-red cutaneous warty growths and nodular excrescences constitutes another remarkable feature of the disease. Usually they are met with in persons who suffer from some active manifestation of the illness. The time which elapses between the appearance of the first symptom and the development of these nodules varies from 3 to 6 weeks; but this may be shorter if the patient had previously suffered from an attack of the disease. It is very curious that the appearance of such cutaneous nodules does not seem to be always related to the severity of the illness; neither does it depend on the intensity of the lesions in the skin. For instance, in a person with marked swelling of the legs and vascular manifestations, there may not be any nodules in the affected parts, whereas they may be seen to develop on the inner aspect of the pinna of the ear or in the skin over the mastoid process where swelling is never noticed. Gravity seems to play

very little part in their formation, as the nodules are mostly situated above the knee.

In the majority of the cases, the number of these nodules is small, varying from a few to a dozen or so; but this is by no means constant. We have seen cases in which there has been

Fig. 4.—The presence of pre-existing inflammation favouring the development of the nodular eruption at that particular site. At the time of an attack of epidemic dropsy, this patient had a small pimple over the area where the nodule developed. There were no other nodules in any other part of the body.

Fig. 5.—A case of epidemic dropsy in which a large number of cutaneous nodules have developed.

only one solitary growth and also others in which their number reached over a hundred (figure 5). Here again, we cannot trace any definite relationship between the number of the eruptions and the severity of the illness. In

Fig 1—A low-power view of a section of skin from a case of epidemic dropsy showing the amount of vascular dilatation in the subcutaneous fatty tissue

Fig. 2—A magnified view of figure 1, showing the fat cells (clean spaces) and dilated capillary blood vessels

Fig 3—Photomicrograph of a section from a cutaneous nodule showing widely dilated vascular spaces along with the angioblastic tissues. The blood vessels are lined by a single layer of endothelial cells. The stroma consists of loose areolar tissue

fact, we have seen instances in which many nodules have been met with in persons complaining of only trivial symptoms. It has also been noticed definitely that an area of skin which had been the site of an eruption in a previous attack of epidemic dropsy is more prone to the development of a nodule during a subsequent attack of the disease. Another peculiarity which has been seen is the special predilection of areas of skin and mucous surfaces which are the seats of a pre-existing inflammation (figure 4). Trauma, irritation due to rubbing of clothes or scratching, a septic nail, ulceration of the gum in pyorrhœa alveolaris, and occasionally inflammation in the nose, are all predisposing factors to the formation of such nodules.

The size of these growths varies widely, from that of a small lentil to a moderately big lemon or a tomato. Usually, they resemble a big pea or a small ground-nut. They may be either sessile or pedunculated; in the latter case, they sometimes drop off when they are inadvertently scratched; this leads to a profuse and often prolonged hæmorrhage. No pain or tenderness is present and sensation is intact though very much diminished. When such a nodule is either pricked with a needle or scratched, bleeding starts and continues. In some cases, the nodules may burst spontaneously; this leads to a very severe hæmorrhage which may continue for hours, or even days. Instances have been seen in which the loss of blood through the rupture of a nodule was so large that the hæmoglobin dropped from normal to 40 per cent.

The morbid anatomy of these cutaneous nodules is very characteristic. When cut, the substance is found to consist of a soft fleshy mass arising from the superficial portion of the skin. On squeezing, a serosanguineous fluid oozes out. In larger nodules, widely dilated spaces may be detected by the naked eye or there may be hæmorrhagic areas. The histological examination of such a nodule reveals the structure of a capillary angioma with marked telangiectasis and containing much angioblastic tissue (plate V, figure 3). In a fairly big nodule from a case of some duration, one notices many widely dilated vascular spaces along with the angioblastic tissue elements. These spaces are lined by a single layer of endothelial cells, but no muscular or elastic tissues can be demonstrated in their walls. This lack of proper supporting structures in the vascular walls appear to be the chief cause of the prolonged bleeding in these cases. All the different stages in the formation of new capillary vessels may be seen in a nodule. There is at first a multiplication of the endothelial cells by mitosis, which may be seen in large numbers in a growing nodule. A vacuole now appears in the cytoplasm of a newly-formed endothelial cell pushing the nucleus to one side. This vacuole enlarges and more nuclei appear surrounding the former till

ultimately it is transformed into a capillary which communicates with the neighbouring ones, as elements of the blood are now seen inside the vacuole. After this formation, the lumen of the vessels is dilated, obviously on account of the pressure of the blood inside them. These vessels, however, remain more or less in an embryonic condition, as even in the case of a very large and widely dilated one no trace of any muscular or elastic elements can be discerned in the wall.

In a nodule which has not been irritated or whose surface epithelium is intact, no evidence of an inflammatory reaction can be seen inside the angioblastic tissues; but, if there is any irritation or if it is infected through a breach of the surface epithelium, and if it ruptures spontaneously and ulcerates, a marked inflammatory reaction may be found on the surface as well as to a considerable depth below. Under such circumstances, the upper portion of the nodules resembles a highly vascular granulation tissue.

From a study of a large series of such nodules from different cases, we have concluded that the primary site of their origin is the superficial layer of the cutis vera in the papillæ of the skin. These areas gradually enlarge and produce a swelling over which the epidermis is found to be stretched as a thin layer. Sometimes a widely dilated blood space may be traced up to this thinned-out epidermis and a mass of blood corpuscles found collected just underneath the covering layer. It will thus be seen how the slightest trauma may lead to the rupture of such a nodule with the escape of a considerable amount of blood from the communicating vascular spaces below. The deeper layer of the cutis vera with the sweat and sebaceous glands presents a normal appearance. In the subcutaneous adipose tissue, however, one may see varying grades of vascular changes depending on the severity of the cutaneous lesions and the duration of the disease.

The development of such nodular growth is not confined to the skin surface only but may also take place in mucous surfaces such as the gum, cheek, interior of the nose, and tongue (figure 6). A pre-existing chronic inflammation in these areas certainly predisposes to such formations although this is by no means always constant. They appear as soft pinkish-white fleshy outgrowths which may grow to a fairly large size. There is very early ulceration, and bleeding takes place on the slightest trauma. The loss of blood from an epulis-like growth of moderate size on the gum may sometimes take on such enormous proportions that it may cause alarming symptoms. A pregnant woman carrying for seven months had an attack of the disease with a few nodules on the skin and a small 'epulis' on the gum; one day whilst taking her meal she injured the growth which bled so profusely and for such a long

time that she became markedly anæmic and aborted. Cases of this nature are often met with in endemic areas.

Although there is so marked a tendency for these outgrowths to bleed, no alteration in the coagulation time of the blood could be shown—the average time being $2\frac{1}{2}$ to 4 minutes. Another important feature of these cases is the behaviour of the skin when the nodules are dealt with by surgical operation. So long as an incision is not made directly over a nodule, there is no abnormal bleeding. Besides, the healing power

Fig. 6.—A nodule on the dorsum of the tongue arising from the mucous surface after an attack of epidemic dropsy. There were no other nodules in any other part of the body

of the skin and mucous surfaces is excellent, as in all our cases in which surgical removal of nodules was undertaken, the healing always occurred by first intention.

The heart.—The effects of the disease are not only present in the skin but also in other parts of the body. It is commonly known that the cause of death in fatal cases of epidemic dropsy is cardiac failure. The heart in such cases has been very critically examined clinically (Chopra and Basu, 1930; Chopra and Bose,

1933), but on account of lack of a sufficient number of necropsy examinations the morbid anatomy and finer histological changes have not been studied as they ought to have been. The very few cases in which the heart was examined after death revealed some very remarkable features. The organ is enlarged, the right side being affected more than the left. The cavities are dilated and their muscular walls are thinner. In one of our cases there was a very interesting condition found in the epicardial layer of fat. It was intensely injected and there were patches which looked like petechial subserous hæmorrhages. No inflammatory exudate could be found, either on the serous surfaces or inside the pericardial cavity, which contained only an excess of clear yellow fluid. When this was subjected to a microscopic study, it was found to show the same type of vascular change as was found in the subcutaneous fat, namely, an increase in the number of the capillaries and their enormous dilatation, some of the latter having almost coalesced, producing a gross picture of 'petechial hæmorrhage'. The individual muscle fibres, both in the left as well as the right ventricles, did not show any detectable evidence of damage but they were widely separated from one another by enormously dilated intermuscular capillaries. Such a histological picture is not met with in any other disease which affects the heart. This wide separation of the muscle fibres obviously leads to inefficient functional capacity as it interferes with an effective and co-ordinated contraction of all the fibres.

The eye lesions.—The occurrence of primary glaucoma in the course of the disease constitutes one of the most distressing features of epidemic dropsy. This complication has been very frequent in the epidemic of this year, over 10 to 12 per cent of the total number of cases having suffered from some degree of it. It is very insidious in its origin and it bears no relationship to the degree of lesions in the skin and other organs. It may come on in a person without any external manifestation of the disease. A house surgeon of the Eye Infirmary of the Calcutta Medical College suddenly complained of typical symptoms of a hyperacute primary glaucoma but no physical evidences of epidemic dropsy could be elicited. On careful inquiry he made the statement that he had a mild attack of the disease 2 to 3 months ago with some swelling of his legs while he was in charge of a subdivision in a district in Eastern Bengal. The onset was so sudden and the symptoms so acute that immediate surgical relief had to be sought.

Out of a small total of 4 cases on which autopsy could be performed, glaucoma was present in only one. The patient died from a congestive type of cardiac failure. Although no cutaneous nodules could be seen, both the skin and the internal organs showed changes

characteristic of the disease. In the eye, the sclero-corneal junction was subjected to a careful histological study but no abnormality of any kind could be detected in it, the channels of absorption including the canal of Schlemm being normal. The ciliary processes, however, showed enormously dilated capillaries with some amount of oedema in the subepithelial connective tissues. Besides this, there was a ring of enormously dilated and engorged blood capillaries lying between the choroid and the sclera. This condition was so very marked that they might be easily mistaken for retinal hæmorrhages, but no actual extravasation of blood could be found under the microscope. How far such pathological changes would contribute to the development of glaucoma is a matter for the ophthalmologists to decide, but there appears to be an altered permeability of the capillaries and an increased functional activity of the ciliary processes, resulting in an overproduction of the aqueous humour which cannot be drained away sufficiently rapidly and which would naturally accumulate, producing an increased intraocular tension.

Other pathological changes.—Epidemic dropsy has a very injurious effect on the female reproductive organs. Let us confine our observations to the changes in the uterus. In the muscular layer one can see many cavernous dilatations of blood vessels lined by a single layer of endothelial cells and the endometrium full of innumerable smaller vessels engorged and dilated as if it were in a hæmorrhagic condition. The stroma is scanty and unhealthy, and the endometrial glands are small and atrophic. In an endemic area of epidemic dropsy, the majority of the infected pregnant women abort and the infected women of child-bearing age hardly ever conceive. These facts can only be explained by the above-mentioned pathological alterations in the muscular as well as the endometrial layer of the uterus, which are brought about by the disease.

The changes in the organs of internal secretion have not been sufficiently investigated. There is undoubtedly increased vascularity and a larger amount of colloid in the anterior lobe of the pituitary gland, but the picture is not so remarkable as to lead to any practical conclusion. The suprarenal in one of our cases showed definite inflammatory reactions mainly around the central vein. A moderate degree of round cell accumulation could also be seen diffusely scattered throughout the substance of the medullary part. This sort of subacute or chronic, diffuse or localized adrenalitis may also be encountered in cases other than those of epidemic dropsy, and unless a sufficient number of autopsy cases are examined the significance of such findings cannot be properly assessed.

The results of the histological examination of the spinal cord and peripheral nerves have

(From the School of Tropical Medicine, Calcutta)

OUTBREAKS of epidemic dropsy do not occur every year; in certain years a widespread epidemic arises followed by a period of quiescence. Further, it has been also noticed that the cases of one epidemic often differ in their severity and chief manifestations from those of another. These variations in morbidity are difficult to explain. During the epidemic of 1926 a large number of patients were seen with skin affections, but these were of rare occurrence in the years 1929 and 1932. During 1934 there was a big epidemic, not only in Bengal, but in the contiguous areas of Bihar and the United Provinces; the Bengalis domiciled in these areas suffering most. Cutaneous manifestations of this disease were seen in cases from every locality and they were more prevalent during this epidemic than in any other we have seen. Erythematous rashes and sarcoids were of common occurrence, and a new type of skin manifestation was observed during the last outbreak; the skin of the exposed parts, especially of the face, was hyperpigmented, and this was most commonly observed during our investigations—which has been discussed in detail in another paper—in Purulia from November 1934 to February 1935.

During the year 1934, 39 cases of epidemic dropsy were admitted into the Carmichael Hospital for Tropical Diseases. Of these 15 showed cutaneous lesions of some form or other;

(Continued from previous column)

been negative. We noticed—a marked gross vascularity of the pia-arachnoid membranes of the cord but the microscopic study of the internal structures did not reveal any abnormality. In the peripheral nerves, we saw definite vascular engorgement in the perineural sheaths, but evidence of neuritis could not be detected.

9 had a rash only, 4 had sarcoids only, 1 had both a rash and sarcoids, while another had a rash and pigmentation.

Clinical types of skin lesions.—T. D., a Hindu male, aged 25 years, teacher by profession, was admitted into the Carmichael Hospital for Tropical Diseases on the 19th September, 1934. He complained of formation of reddish nodules on different parts of the body and swelling of his legs. He stated that he had had the nodules for one month and the swelling for a fortnight only. The swelling was particularly marked in the evening after the day's work. Palpitation of the heart was experienced occasionally. He also complained of vague pains the distribution of which was variable. There was nothing particular in the past history excepting a few attacks of dysentery. Several members of his family were also suffering from epidemic dropsy.

Examination.—The most striking feature of the case was the presence of vascular nodules on the skin. They were altogether fifty-one in number irregularly distributed over different parts of the body. They were more numerous on the trunk than on the extremities. All of them were said to have started as minute red papules, which gradually grew bigger and more vascular. Some were as big as a small marble. Most of them were sessile, and only three were pedunculated. They were rather irritable; sometimes he had scratched them, and they had bled profusely. One of the pedunculated growths was fungating and covered with sloughs which bled on manipulation. Some were noticed to be healing with formation of scabs.

Oedema was present in both legs below the knee and there was pitting on pressure. There was no tenderness on pressure or pain in the calves.

The apex of the heart was slightly displaced outwards. The first sound in the mitral area was accentuated and there was a faint systolic bruit at the base. The pulse rate was 80 per minute, systolic blood pressure 100 and diastolic 70 mm. of mercury. The electrocardiogram showed T-P interval greatly reduced showing that the heart was not getting proper rest. R-wave was splintered; this was possibly due to delay in the rate with which the impulse was propagated to the ventricles. Orthodiagram showed a well-marked enlargement of the left ventricle and right auricle. The knee jerks were normal on both sides; the pupils were equal and reacted to light and accommodation; and the field of vision and the tension were normal.

Cultures made from the stool showed numerous Gram-positive bacilli; the blood and the urine were sterile. The blood count was as follows: leucocytes—9,800, hæmoglobin—75 per cent, erythrocytes—3,820,000, polymorphonuclears—62 per cent, small mononuclears—30 per cent, large mononuclears—1 per cent, eosinophiles—7 per cent. The coagulation time of the blood was 1½ minutes. The Wassermann reaction was moderately positive. Blood calcium, uric acid and cholesterol were 12, 4 and 180 mg. respectively per 100 c.cm. of blood.

The presence of sarcoids was the chief cutaneous sign in this case. These were fifty-one in number and their distribution was irregular. They were of various types, *viz.*, sessile, pedunculated, ulcerated and fungating. Bleeding and sepsis were common complications and the healing process with scab formation was observed. There was no further formation of sarcoids when once the treatment was started.

(2) M. H., a Mohammedan male, aged 26 years, a railway ticket collector and a resident of Howrah, was admitted on the 24th September, 1934. He complained of fever, redness of the skin, palpitation and swelling of legs. He had a preliminary attack of diarrhoea about one and half months before and then these symptoms appeared, the sequence of which could not be properly ascertained from the patient. There was nothing special in his previous history. One servant and

another member of his family were attacked with epidemic dropsy a little before he got the attack.

Examination.—A generalized erythema or flush was the most striking feature of this case. It was most marked over the extremities and abdomen (*see* plate VI) and was associated with a hot burning sensation; it was purple in colour. The oedema was most marked about the middle of the legs and subsided a few days after admission. There was no sarcoid formation anywhere on the skin. He had an irregular type of fever which persisted for about two weeks after admission into the hospital. The apex of the heart was half an inch outside the normal site and there was a mitral systolic bruit. The pulse was rapid and the blood pressure 100/50 mm. of mercury. Orthodiagram showed enlargement of left ventricle and right auricle. Electrocardiogram showed shortened T-P interval. Crepitations were present at the bases of both lungs; the liver was palpable and tender; no abnormality was detected in other organs. The stools showed hookworm ova and Gram-positive bacilli on culture. The urine and blood cultures were sterile. There was excess of urobilin in the urine. The blood count was as follows: hæmoglobin—70 per cent, leucocytes—7,400, erythrocytes—3,920,000 per c.mm., polymorphonuclears—70 per cent, small mononuclears—18 per cent, large mononuclears—3 per cent, eosinophiles—9 per cent. The coagulation time of the blood was 2 minutes. Blood calcium, uric acid and cholesterol were 9, 2 and 135 mg. respectively per 100 c.cm. of blood.

This is an acute case with generalized rash and other manifestations of epidemic dropsy. The flush on the skin was a most striking feature and was purple coloured. There was no sarcoid formation in spite of the extensive erythema of the skin.

(3) B. P., a Hindu male, aged 30 years, blacksmith by occupation, was admitted on the 25th December, 1934. His complaints were (i) swelling of the legs for about one and half months, (ii) small red nodules in different parts of the body, (iii) pain in the calves, and (iv) rash on the legs. The patient used to live in a mess where there had been several cases of epidemic dropsy. On examination seven sarcoids were found scattered in different parts of the body. Most of them were of the size of a pea. One was on the toe (*vide* plate VII) in which there was an extravasation of blood which subsequently turned black and hard. There was mottling of the skin on the inner aspect of thighs; the rash on the legs was patchy in distribution. Heart:—The apex was in the normal site and there was a systolic murmur in the pulmonary area. The pulse was rather rapid; the blood pressure was 120/65 mm. of mercury. Orthodiagram showed a slight enlargement of the left ventricle and right auricle, the electrocardiogram was normal. No abnormality was detected in other systems. Hookworm and ascaris ova were found in the stool and Gram-positive bacilli were isolated from it. Microfilariae were found in the blood. Bacterial culture of the blood and urine was sterile. There was an excess of urobilin in the urine. Blood calcium, uric acid and cholesterol were 10, 4 and 135 mg. per 100 c.cm. of blood. The blood count was as follows: leucocytes—6,400, erythrocytes—3,120,000 per c.mm., hæmoglobin—65 per cent, polymorphonuclears—79 per cent, small mononuclears—17 per cent, and eosinophiles—4 per cent.

The peculiarity of this case is the simultaneous occurrence of rash and sarcoids. There was apparently hæmorrhage inside one sarcoid, which turned black, dry and hard. The rash on the legs was patchy and looked like freckles.

(4) B. B., a Hindu male, aged 35, a business man, was admitted into the hospital on 30th December, 1934, with the complaint of slight swelling of the legs, rash, especially on the legs, and pigmentation of face

PLATE VI

PLATE VIII

Epidemic dropsy: pigmentation

PLATE IX

Epidemic dropsy: composite picture of cutaneous manifestation

(vide plate VIII). The disease started a month before his admission with diarrhoea and fever which was of a low irregular type. Later, his legs became swollen and painful and subsequently a rash appeared on them. He also noticed a peculiar change in his complexion especially on his face which became much darker than normal. All the members of his family were attacked with epidemic dropsy, but his case was peculiar in that he alone had marked pigmentation on the face. A soft systolic murmur was heard in the mitral area, and the patient complained of palpitation. The liver was slightly palpable and tender. The systolic blood pressure was 120 mm. and diastolic 75 mm., hæmoglobin—75 per cent, erythrocytes—4,120,000, leucocytes—9,200 per c.mm., polymorphonuclears—83 per cent, large mononuclears—2 per cent, small mononuclears—14 per cent, and eosinophiles—1 per cent. Blood calcium, uric acid and cholesterol were 10.5 and 187 mg. respectively per 100 c.cm. of blood. Microfilariae were found in the blood. The patient complained of seeing haloes round the light at night, but the tension in the eye was normal and the fundus oculi was healthy on ophthalmoscopic examination. The knee jerks were normal and there was no calf tenderness. The patient also complained of painful defæcation. Rectal examination showed piles and anal fissures. During his treatment in the hospital the colour of his face became less dark with the improvement in his general condition.

Pigmentation and rash were the most interesting cutaneous features of this case.

Discussion

Apart from œdema, which has been dealt with in detail by the senior author in previous papers, sarcoids, rash and pigmentation are the most important skin manifestations of this disease. Sarcoids are fleshy growths, angiomatous in nature, occurring in certain epidemic dropsy cases, and were first studied and described by Acton in 1927. Their number is variable and their distribution on the body is most irregular. They are not limited to the skin, but may occur on the mucous membrane. We noticed them on the palate and gums of a patient in the out-patient department. The size of the growths is variable and they are not usually tender nor painful. When there is secondary infection they become very irritable and when scratched or injured bleed profusely. Attempts were made to study clinically the different stages through which a sarcoid may pass. Commonly it begins as a tiny red papule, which gradually increases in size. The biggest we have so far seen was about $1\frac{1}{2}$ inches in diameter; it was situated in the mammary region. After a variable period the growth begins to dry up and disappear. Scales are often formed on the surface during this process and if the scales are rubbed off the bright red sarcoid becomes visible again. This process goes on till the whole sarcoid is dried up leaving a pigmented area. Large sarcoids are prone to be pedunculated and to become infected with secondary organisms. Severe hæmorrhage is a common complication which aggravates the anæmia of the patient. Ulceration may occur following sepsis.

Plate IX is a composite illustration of the stages of sarcoids observed by us. Nodules

numbered 1, 2, 3 and 4 are growing stages. The healing stages (nos. 5, 6 and 7) are not infrequently associated with fine scale formation and some irritation. Finally, healing is completed by the shedding of the scabs which leave behind a small pigmented area (no. 8). Sometimes, instead of passing on to the healing stage a sarcoid grows bigger and becomes pedunculated. Constriction at the pedicle is liable to interfere with the blood supply and this along with secondary infection often gives rise to ulceration.

The production of a sarcoid is due to formation of new capillaries, but the reason why this proliferation occurs is not clearly known. It is possible that while the toxin of epidemic dropsy causes generalized capillary dilatations, it may also give rise to local irritation and proliferation of endothelial cells with formation of new capillaries thus giving rise to sarcoids.

Flushing of the skin has also been represented in the diagram. Finger marks on the right thigh show how the flush fades on pressure and reappears soon after the pressure is removed. It may be generalized or localized in particular regions of the body. Sometimes it occurs in small patches only. Peculiar mottling of the skin especially on the inner aspects of the thighs is very common. The production of the flush is due to widespread dilatation of the capillaries of the skin.

A new cutaneous manifestation observed during the present epidemic is the hyperpigmentation of the skin of certain parts of the body. The exposed parts, namely the face, hands, and feet, are chiefly affected. Two types of pigmentation have been observed, a generalized form, the face, the neck and the limbs turning uniformly dark and a patchy form, the pigmentation being most marked on the forehead and the cheek bones, and simulating kala-azar pigmentation.

Treatment.—Rash and pigmentation did not require any special treatment. They gradually fade as the patient improves under general treatment. Sarcoids required special attention in certain cases which were complicated with hæmorrhage or sepsis. Bleeding sometimes stopped with pressure only, but recurrence was quite common. We treated a few small bleeding sarcoids with carbon dioxide snow; there was no further oozing and the sarcoids gradually dried up. Big and pedunculated tumours were always removed under novocaine, and the wounds healed by first intention.

Summary

1. The chief features of one outbreak of epidemic dropsy often vary from those of another.

2. Four cases of epidemic dropsy with different types of cutaneous manifestations have been described.

(School of Tropical Medicine, Calcutta)*

ACTON AND CHOPRA (1927) pointed out the increased vascularity of the subcutaneous fatty tissue in cases of epidemic dropsy. Acton (1927) further studied the condition in detail and noted that there is marked dilatation of all the blood vessels of the skin in different areas. The venules of the subcutaneous fatty tissues were seen to be large and dilated, at first looking as if hæmorrhages had taken place in this area. Under the epidermis he noticed proliferation of endothelial cells around these dilated vessels. He also made a special study of the vascular nodules often occurring in these cases and concluded that they are new angiomatous growths of an innocent nature. They are acquired as the result of irritation of the intima of the vessels in the different skin layers by some 'septic' condition in the gut either due to bacteria or toxins. These are commonly called sarcoids. Acton referred to the workers Kaposi (1872), Boeck (1905), Darier and Roussy and criticized the name sarcoid as an unfortunate one for these lesions bear no relationship or resemblance to the sarcomata. Shanks and De (1931) observed extrême and widespread dilatation of the capillaries, which were seen more abundantly in the fatty tissue of the stratum subcutaneum.

The above observations prove that the essential lesion consists of widespread dilatation of the blood vessels of the skin. This vascular phenomenon is responsible for the erythema, œdema, and formation of sarcoids in epidemic dropsy cases.

During the epidemic of 1934 we saw a large number of cases characterized by these signs. We had the opportunity of obtaining biopsy material from cases treated in the Carmichael

Hospital for Tropical Diseases. Sections were prepared from the 'flushed skin' of different patients and also from sarcoids of various types and stages of development. In this paper we intend to describe briefly the histopathology of some of the more typical sections of these cutaneous manifestations.

The microscopic appearance of the tissues will be considered under five headings:—

1. *Histopathology of simple erythema with œdema (plate X, figures 1 and 2)*

The epidermis is normal. The basal layer shows a heavy deposit of melanin pigment, which is seen interspersed among the deeper cells of the rete. There is papillary and inter-papillary œdema of the corium, the majority of the papillæ appearing very wide, in some places almost flattened out. There is marked dilatation of the papillary and subpapillary blood vessels with perivascular infiltration which consists mainly of endothelial cells. The connective tissue is œdematous and blood vessels in all the levels of the skin are dilated. The sebaceous and sweat glands are quite healthy. In the subcutaneous tissue the fine blood vessels supplying the individual fat lobules are moderately dilated and show perivascular infiltration of the same nature as in the more superficial area. There is no evidence of extravasation or actual hæmorrhage in any portion of the tissue.

The general survey of the tissue under low power (magnification 10 × and 2/3 Ziess) shows isolated patches of cellular masses in the corium and also the subcutaneous tissue. These masses are distinctly perivascular in distribution and their nature is non-inflammatory, the main bulk consisting of the endothelial type of cells only.

2. *Histopathology of the early stage of a sarcoid (plate X, figures 3, 4 and 5)*

The epidermis is normal. The basal layer shows a fairly heavy deposit of melanin, some of the cells of the rete also show melanin pigment especially in the deeper layer. The corium shows œdema both papillary and sub-papillary in distribution. The subpapillary plexus of vessels are distinctly seen, there is very slight perivascular infiltration. A little deeper down in the corium areas of proliferating endothelial cells with formation of a large number of young blood vessels is seen. The intervening collagen bundles of the connective tissue appear œdematous. The limitation of this new endothelial cellular mass is not distinct and is apparently diffused to an uncertain depth in the corium. There is no fibroblastic reaction. Sweat and sebaceous glands are normal in structure. This diffuse proliferation of endothelial cells is distributed in small isolated patches in the more superficial portion of the corium; the deeper portion is unaffected.

(Continued from previous page)

3. Erythema, sarcoids and hyperpigmentation are the important cutaneous manifestations that have been discussed.

4. An attempt was made to study the stages of sarcoids.

5. Pigmentation is a new feature which requires further investigation.

6. Treatment has been described.

PLATE X

Fig. 1

Fig 2

Fig. 3

Fig. 4

Fig. 5

3. *Histopathology of the nodular type (plate XI, figures 6 and 7)*

In the region of the sarcoid the horny layer of the epidermis is markedly thinned out and the papillæ are flattened. There is considerable œdema of the papillary and subpapillary portions of the corium; the collagen bundles look myxomatous owing to the separation of the fibres by œdema. There is marked proliferation of the endothelial type of cells with no inflammatory cellular exudate. The subpapillary and cuticular plexuses are dilated and show perivascular infiltration. This change is seen extending deep into the corium as far as the level of the sweat glands. Sebaceous and sweat glands are absent in the region of the main tumour mass. Diffuse patches of endothelial cellular proliferation and formation of new vascular twigs are noticed at different levels in the corium. At the junction of the unaffected area with this new sarcoid formation the horny layer is thickened, there is enormous hypertrophy of the rete which is seen as finger-like projections extending deep into the corium almost to the level of the sweat glands. This hypertrophy of the epidermis (plate XI, figure 6) seems to be nature's way of limiting the process. A fully-formed sarcoid at this stage (plate XI, figure 7) contains newly-formed blood vessels of different sizes and a few connective tissue cells but no fibroblasts nor any inflammatory cellular exudate.

4. *Histopathology of the fungating or ulcerative type (plate XI, figures 8 and 9)*

In the epidermis the prickle-cell layer is markedly œdematous; the nuclei are indistinct in the more superficial portion. In some places the upper portion of the rete is separated from the horny layer by formation of a large vesicle containing a few polymorphonuclear leucocytes. In other places the superficial part of the rete shows degenerative changes with infiltration of round cells and polymorphonuclear leucocytes leading on to ulcerative changes in the epidermis. Throughout the affected area the cells of the rete are seen to undergo degenerative changes by the formation of large vacuolated spaces with polymorphonuclear infiltration in the immediate vicinity. Apparently there is a good deal of leucorrhæxis and a certain amount of erythorrhæxis without any actual hæmorrhage. (In one portion of the affected area actual extravasation and hæmorrhage were seen which may have been due to some injury of blood vessels by external agents.) The basal cells are devoid of pigment. The subpapillary vessels are engorged and a few of them show thrombi. The corium is œdematous; the collagen bundles are separated from each other giving it a myxomatous appearance. The deeper portions are hæmorrhagic. There is also formation of a network of young blood vessels. The hilum of the tumour mass is also hæmorrhagic and the

connective tissue elements are markedly œdematous. The fibrils running from the deeper portion towards the surface are accompanied by twigs of newly-formed blood vessels which are also engorged.

These pedunculated sarcoids very often undergo ulcerative changes. Trivial injuries cause rupture of the œdematous and degenerated epidermis and allow free flow of the extravasated blood—hence the name 'bleeding vascular mole'.

5. *Histopathology of healing sarcoid (plate XI, figures 10 and 11)*

The epidermis is represented by only one or two layers of flattened cells of the rete, the deepest ones containing a little pigment. The superficial horny epithelium is seen to undergo thickening and is detached from the subjacent layer. The papillæ are flattened out and there is a marked œdematous condition of the corium. The subpapillary vessels are markedly enlarged and those in transection are seen packed with red blood corpuscles. A large number of ramifying newly-formed blood vessels, the walls of which consist of a single layer of endothelial cells, are seen distributed throughout varying depths of the corium. There is no evidence of perivascular infiltration around these newly-formed blood vessels and there is no evidence of inflammatory cellular exudate in any portion of the sarcoid. In the younger portion changes in the epidermis, similar to those already mentioned, are noticed. In one area there is extravasation and actual hæmorrhage in the subcuticular region where the colloidal degenerative changes have already commenced. The fibres of connective tissue near the hilum are seen running parallel with the newly-formed twigs of blood vessels. The connective tissue is also seen undergoing patchy colloidal degeneration in this region. There is no evidence of fibrotic changes in the region of the pedicle. A

DESCRIPTION OF PLATE X

Figures 1 and 2.

Erythema with œdema.

Figure 1.—Normal epidermis, the basal layer being packed with melanin pigment. Patchy dilatation of subpapillary blood vessels with slight perivascular infiltration. The dilated vessels are packed with red blood cells. Slight papillary and subpapillary œdema.* (Magnification 10 × and 2/3.)

Figures 3, 4 and 5.

Early sarcoid.

The papillæ are partly flattened. Basal layer rich in pigment (figure 4). Œdema of papillary and subpapillary portion of corium (figures 3, 4 and 5). Marked proliferation of endothelial cells and formation of a large number of young blood vessels well marked in figures 4 and 5 with a single endothelial lining. Œdematous collagen bundles. (Magnification 10 × and 2/3.)

* Blood vessels supplying the fat lobules are dilated (figure 2).

considerable number of the finer twigs of newly-formed blood vessels are seen to be undergoing thrombosis. This histopathological picture is suggestive that the new formation is of non-infective origin.

Discussion.—This study shows that the vessels of the skin are first dilated; then there is an endothelial proliferation, which may finally lead to formation of new blood vessels. Increased vascularity is chiefly responsible for the production of the swelling and erythema. As a rule the erythematous rash is more pronounced when the superficial vessels are involved in the change. In some sections of the 'flushed skin', the capillaries were seen dilated in all the layers of the corium, and the venules in the subcutaneous tissue were comparatively less dilated. The corium is sometimes very much thickened with all its vessels dilated and engorged with blood. Endothelial proliferation is particularly noticed in early sarcoid formation and, when this proliferation goes on for some time, new blood vessels are formed with multiple blood sinuses giving the appearance of an angioma.

We made an attempt to find out whether the skin lesions, especially the sarcoids, are of infective origin. No growth was obtained in cultures. Inoculation into monkeys was not followed by any reaction or symptoms. Two of us inoculated ourselves with an emulsion of sarcoids, but the results were negative. These results rule out the possibility of direct contagion.

Our thanks are due to Dr. K. P. Banerjee, M.B., D.T.M., Assistant Professor of Pathology, Calcutta School of Tropical Medicine, for his help in studying the histological changes.

Summary

The histopathology of various cutaneous lesions has been described.

(Continued at foot of next column)

DESCRIPTION OF PLATE XI

Figures 6 and 7.
Nodular sarcoid.

Thin horny layer, flattening of papillæ, papillary and subpapillary œdema (figure 7). Marked endothelial proliferation as also marked dilatation of subpapillary and cuticular vessels (angioblastic tissue) with walls being lined with a single layer of endothelium. (Magnification 10 × and 2/3.)

Figures 8 and 9.
Fungating sarcoid.

œdematous prickly cell layer and infiltration of round cells and polymorphonuclear leucocytes in the epidermis. Leucorrhæxis and erythorrhæxis (figure 8). Dilated vessels showing thrombi (figure 8). Formation of vesicles (figure 9). (Magnification 10 × and 2/3.)

Figures 10 and 11.
Healing sarcoid.

Thin epidermis. Thickened horny layer with vesicle formation and hæmorrhagic exudation. Colloidal degeneration with hæmorrhage (figure 11). Thrombosis of some of the new blood vessels. (Magnification 10 × and 2/3.)

OBSERVATIONS ON EPIDEMIC DROPSY CASES ADMITTED INTO THE TROPICAL DISEASES HOSPITAL FROM 1922 TO 1933

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

S. N. BHATTACHARYA, M.B., D.T.M.
Registrar, Carmichael Hospital for Tropical Diseases

In the present paper, we have attempted an analysis of the cases of epidemic dropsy admitted into the Carmichael Hospital for Tropical Diseases from the time of its opening in 1922 to the end of the year 1933. During this period a total of 131 cases of the disease were admitted; of these the largest number, *i.e.*, 39, was admitted in the severe epidemic year of 1926. In 1932 when the epidemic was also fairly severe 23 cases were admitted and treated. In between these two epidemic years, we had a slight rush of patients in 1929, when the admission curve (*vide* annual curve) rose above the average. In other years, the admissions were below the average except in 1924 when the curve just touched it with 11 admissions. The period under review is too short to draw any conclusion regarding the periodicity of the epidemics, but certain points in the curve are striking. The curve consists of a series of sharp peaks and deep valleys; there is no high plateau anywhere in the curve. This shows that a severe epidemic in a year was usually followed by a period of quiescence.

Seasonal incidence.—A grouping of the cases month by month shows some interesting features.

Here a short statement regarding the seasonal variations of this province will not be out of place. Between the months of November and February Bengal has very little rainfall while the prevalent wind is the dry and cold north-western monsoon. During the months of March, April, May and the first two weeks of June, the province is visited by heavy thunderstorms; the prevalent wind during this period is the hot and comparatively humid south-eastern monsoon. The rainy

(Continued from previous column)

The chief changes consist in dilatation of blood vessels in all the layers of the skin, proliferation of endothelial cells around the dilated vessels, and sometimes formation of new capillaries which give rise to sarcoids.

The lesions are not infective.

season starts by the middle of June and extends to the middle of October, though the heaviest fall occurs between June and September.

A study of the monthly admission curve shows a sharp rise from June to the maximum in August. Then it falls nearly as rapidly to October and more gently through the cold weather months to zero in April. The shaded portion of the figure indicates the rainy season of the year. It is quite apparent that the epidemics were most prevalent during the rains and immediately after it. During the cold dry months, a few patients were admitted but these were the remnants from the preceding epidemic. There were no admissions during the two months immediately following the dry, cold season, i.e., April and May, and only two admissions in the month of June. These observations extending

GRAPH I

over a period of twelve consecutive years show a distinct relationship between the occurrence of an epidemic and the rainy season.

Age incidence.—Epidemic dropsy is a disease affecting the people at the prime of life. Out of 131 cases of this series, 16 were in the first decade, 39 in the second, 42 in the third, 22 in the fourth, 8 in the fifth, 3 in the sixth, none in the seventh, and a solitary case in the eighth decade. The lowest age observed in our hospital was in a patient two years old.

Sex.—It is not possible to give any opinion about the sex incidence of the disease from our figures, as the ratio is influenced by the ratio of available male and female beds of the hospital, and the number of the latter is comparatively much smaller. But our general experience of the disease goes to show that males and females in a family are equally attacked by the disease.

Race.—Epidemic dropsy is a disease of rice-eating people. In our series there were 94 Bengalis, 21 Anglo-Indians and Europeans (all

rice and curry eaters), 8 from Bihar and the United Provinces, who while in Bengal take at least one meal of rice during the day, 2 Jews

GRAPH II

GRAPH III

and 2 Nepalis, 1 Oriya, 2 Chinese and 1 Assamese.

When classified according to their religion, there were 64 Hindus, 43 Christians, 20 Mohammedans and 4 of other castes. Our series

showed a proportionately large number of Bengali Christians admitted for this disease.

Symptoms.—The patients admitted showed a variety of symptoms during the onset. The commonest of these were œdema (66), diarrhœa (41) and fever (25); many of the patients showed a combination of the above symptoms. Eleven patients started the disease with heart symptoms; of these six complained of palpitation, four of dyspnœa and one of cardiac pain. One patient complained of vague pains in the abdomen at the outset, another had a red rash on the lower limbs and two had severe pains in the legs.

The main symptoms manifested by the patients are grouped under the following heads: (1) œdema, (2) diarrhœa, (3) fever, (4) cardiac symptoms, (5) nervous symptoms, (6) cutaneous symptoms, and (7) eye symptoms.

œdema.—This was the commonest manifestation of the disease in this series and, out of the total of 131 cases, 125 suffered from œdema some time or other during the course of their illness. The commonest sites were the lower extremities, but very often the hands and the trunk were also affected. The œdema was usually of solid type especially in the early stages. Tenderness and redness of the affected parts were common features.

Diarrhœa.—Eighteen patients suffered from diarrhœa at the onset only and 47 cases suffered from it off and on during the course of the illness. Only 13 patients had constipation. The incidence of diarrhœa was more common during the severe epidemic years when more acute cases were admitted into the hospital. For instance, 65 per cent of patients had diarrhœa in 1927, 70 per cent in 1929 and 56 per cent in 1932, while the average percentage of diarrhœa in non-epidemic years was 27 per cent only.

Fever.—Out of 131 patients in this series, 94 had some rise of temperature during the course of the disease, while 37 were absolutely afebrile. Out of these 94 cases, 9 had short periods of fever during the onset only, but the majority (60 in this series) ran a low irregularly-intermittent temperature during the progress of the illness; the temperature settled down with the amelioration of other symptoms. In 12 patients the temperature instead of being intermittent was of a low remittent type. One patient had a high remittent fever for a short period due to an intercurrent attack of influenza. Three patients in 1932 had a high irregular temperature, and in two of these malarial parasites were found in the blood. In seven cases the temperature curves showed an occasional high rise and of these four proved to be due to malarial infection. One severe case in 1926 ran an up-and-down temperature of a septic type. As in case of diarrhœa the percentage of patients suffering from fever also increased during the epidemic years, being 66 per cent, 92 per cent and 95 per cent in 1926,

1929 and 1932, respectively. The average percentage of fever in non-epidemic years was 38.

Cardiac symptoms.—An analysis of the cardiac manifestations showed multifarious symptoms. For convenience the patients were classified into four broad groups, (1) those with grave symptoms, (2) those with moderately severe symptoms, (3) those with slight symptoms, and (4) those in which no cardiac symptoms were present. Those patients who showed intense venous engorgement, dilated heart, embryonic rhythm, orthopnœa and similar symptoms of acute cardiac failure were classified as grave; those classified as moderate had such symptoms as dyspnœa on slight exertion, palpitation, systolic hrûit, moderate dilatation of the heart and other signs of partial failure. Those classed as slight only complained of occasional palpitation, without any detectable organic defect; a few patients had no cardiac trouble at all. In this series there were 13 patients with no cardiac symptoms, 19 cases with slight, 66 with moderate, and 33 with marked evidence of cardiac insufficiency.

As has been observed in two previous papers (Chopra and Basu, 1930, and Chopra and Bose, 1933) the chief cardiovascular symptoms of this disease are anæmia and tachycardia which are fairly constantly present, their degree varying with the severity of the disease.

Nervous symptoms. *Knee jerks.*—In 59 patients there was no alteration in the knee jerks; in two they were diminished; in 17 they were lost. Both knee jerks were increased in 39 patients, while in 14 patients they were manifestly unequal.

Other nervous manifestations were pain and tenderness in the limbs and these were present in 47 patients in this series. Only in three cases weakness and numbness of the lower extremities were complained of.

Cutaneous symptoms.—General flushing of the skin and a petechial rash of the affected limbs and often over the trunk were the commonest skin conditions met with, and in this series there were 26 of the former and 13 of the latter. Another interesting skin manifestation was the appearance of tiny scarlet nœvoid growths, 'sarcoids'. Six patients of this series showed these growths in their bodies. The cutaneous symptoms were comparatively more prominent in the epidemics of 1926 and 1932 and during both these years 48 per cent of the patients showed these lesions.

Eye symptoms.—In some epidemics series of ophthalmoscopic examinations were carried out. Seven patients showed cupping of the disc, three patients had retinal hæmorrhage and one engorgement of the retinal veins. In two patients the only ocular symptom was an increased tension.

Laboratory examinations.—Routine examinations of the stools and the blood of the patients were carried out for any concurrent pathological

condition. Hookworm ova were found in 28 cases, while 6 cases showed ascaris infection. Only one case had *E. histolytica* in the stools; 8 patients had malarial parasites in the blood; and 7 had microfilariæ.

Treatment.—A rice-free diet and rest in bed were the two important factors in the treatment in this series. Rice in any form was withheld from the patients and a diet rich in proteins was given throughout the illness and well into the convalescent period. Perfect rest in bed was insisted upon to give the heart as much rest as possible. Twenty-two patients in this series were treated only with rest and rice-free diet with quite satisfactory results.

A large number of drugs were tried. Digitalis was tried in 25 cases, strophanthus in 7, caffeine in 4. Calcium was given intravenously in 9 cases, and by the mouth in 12 with extract of parathyroid. Iron alone was given in 13 cases, iron with strychnine in 49 and with arsenic in 6. Adrenalin alone or with pituitrin was administered in 31 patients and lately tincture of ephedra was given by mouth in 28 cases with a view to controlling cardio-capillary crises.

With regard to details of the comparative usefulness of these drugs, the reader's attention is drawn to the previous paper (Chopra and Bose, 1933).

The digitalis group of drugs was of little value in relieving cardiac symptoms of epidemic dropsy. Capillary constrictors, such as adrenalin or ephedra, preferably combined with a nerve tonic, such as strychnine and a hæmatinic, such as iron, gave the best results. In acute cases with intense venous engorgement blood-letting was tried to relieve the cardiovascular system. This procedure often helped the patient to get over a crisis and thus saved several lives.

Results.—In this series of 131 cases there were 9 deaths; 75 patients were discharged as cured, 35 as relieved, and 14 were discharged without marked improvement.

Summary and conclusions

Epidemics of this disease do not recur year after year; the disease is at its worst during the rains. It generally affects both sexes at the prime of life, and, so far as our observations go, only rice-eating races are affected. In this series, although the number of Mohammedan patients is much less than that of Hindus and Christians, the proportion of Mohammedans to the other two religious groups is the same amongst epidemic dropsy cases as amongst the whole hospital population. The Mohammedans, however, form 55 per cent of the total population of the province, but the bulk of them are cultivators and field labourers. It would appear that the disease is pre-eminently one of the middle-class people.

Œdema, diarrhoea and fever are the commonest symptoms at the onset; the cardiac and

other symptoms are nearly always later complications.

As the name of the disease implies, œdema is almost a constant feature. Fever and bowel complications are frequent symptoms of the disease, particularly during severe epidemics. The heart is nearly always affected with more or less severity. The knee jerks are variable, but an increase in the jerks is the commonest variation. Neuritic pains and tenderness of the affected limbs are important nervous manifestations; the eye symptoms are variable and in certain epidemics a large number of patients suffered from glaucoma while in others there were less. Flushing of the affected limbs and in certain cases a hæmorrhagic rash may be encountered. Sarcoids are an interesting skin phenomenon of the disease.

The most important factors in treatment are (1) rice-free diet, and (2) rest in bed. The digitalis group of drugs is of little value in the cardiac failure of epidemic dropsy. Adrenalin and pituitrin injections give temporary benefit and are useful in averting cardio-capillary crises. Tincture of ephedra vulgaris introduced by the senior author combined with calcium lactate has lately proved efficacious. In our series the death rate was 6.87 per cent.

THE INCIDENCE OF CEREBRO-SPINAL FEVER IN THE BORSTAL INSTITUTION AND CENTRAL JAIL, LAHORE, DURING 1934, WITH A NOTE ON THE USE OF ANTI-MENINGOCOCCUS PROPHYLACTIC VACCINE

By M. YACOB, M.B., B.S., DR. P.H., D.P.H., D.T.M. & H.
Epidemiologist to Government, Punjab

THE work in connection with the suppression of cerebro-spinal fever in the Lahore jails was continued during the year 1934.

The total number of post-nasal swabs examined during the year was as follows:—

	Number of swabs	Number of carriers detected	Percentage carrier rates
Borstal Institution, Lahore.	3,950	19	1
Central Jail, Lahore.	2,652	21	1.5
TOTAL ..	6,602	40	

The procedure adopted consisted of swabbing all the new entrants who were not allowed to mix with the general jail population until they had been declared negative. In addition, swabs of contacts were also examined as soon as any case occurred. The prisoners who were under transfer to the Andamans and other jails were also swabbed and not allowed to leave till they had been declared non-carriers.

The Borstal Institution, Lahore

Cases of cerebro-spinal fever continued to occur in the Borstal Institution during the year 1934. In all 34 cases with 10 deaths were reported. The distribution of these by months is shown in the chart below.

It will be seen that the largest number of cases occurred during the months of January, February, March and November, namely, 9, 5, 6 and 6, respectively.

The Central Jail, Lahore

During the year 6 cases and 4 deaths occurred from cerebro-spinal fever in the Central Jail, Lahore, one each in January and February, three in March, and one in August. This last patient had been released temporarily on 2nd August, but was admitted nine days later as a fulminating case of cerebro-spinal fever.

Preventive measures

The general scheme of prophylaxis consisted in keeping in quarantine all fresh admissions

to the jails until their post-nasal swabs had been examined and found negative for the meningococcus, isolation of the sick and of carriers, segregation of contacts, adoption of general measures for the avoidance of overcrowding and the use of 1 in 5,000 solution of potassium permanganate in normal saline for gargling and for sniffing up the nose.

In addition, the prophylactic inoculation of prisoners with anti-meningococcus vaccine was also carried out. A quantity of vaccine, prepared at the Central Research Institute, Kasauli, was obtained through the courtesy of Lieutenant-Colonel J. Taylor, D.S.O., I.M.S., the Director of the Institute, for the purpose of conducting a controlled experiment amongst the prisoners of Lahore jails to ascertain the immunizing value of the vaccine. With this object the population of both the jails—the Borstal Institution and the Central Jail—was divided into approximately two equal portions. One portion was inoculated with the vaccine, whilst the other was left as a control. Both portions were otherwise kept under identical conditions as regards work, sleep and general environment, etc.

The vaccine was administered at weekly intervals in three divided doses of 0.5 c.cm., 1 c.cm. and 2 c.cm. to each prisoner. Altogether 1,769 individuals were inoculated, 1,002 in the Central Jail and 766 in the Borstal Institution; of the latter group 46 received only two and 55 only one injection.

Up to date (April 1935) 6 cases of cerebro-spinal fever have been reported in the Borstal Institution amongst the non-inoculated group and none from the inoculated group. In the case of the Central Jail, however, one fulminant case of cerebro-spinal fever which proved rapidly fatal was reported from the inoculated group in addition to an imported case from Lahore district.

Reactions following inoculations.—There was some constitutional disturbance consisting of headache and a rise of temperature varying between 99.5°F. and 100.5°F. in about 60 per cent of the prisoners after the first inoculation. A few prisoners also complained of pains in the joints. The reaction progressively decreased in severity with the second and third inoculations.

The reactions, both general and local, were in no case so severe as to incapacitate a person from doing his work for more than a day.

Immunizing value of the vaccine.—The number of cases of cerebro-spinal fever that have so far been reported from both the jails are all amongst the non-inoculated with the exception of the one fatal case reported from the inoculated group in the Central Jail, Lahore. The number of cases, however, is so small that no significance can be attached to the result and it is not possible to express an opinion as to the

(Continued at foot of opposite page)

A SHORT ACCOUNT OF TEN CASES OF ECLAMPSIA TREATED BY INTRA-VEINUS INJECTIONS OF MAGNESIUM SULPHATE

By M. M. NOLAN, M.Ch., M.A.O., F.R.C.S.I.,
M.C.O.G., W.M.S.

Ishwaria Memorial Hospital, Benares

DURING the past winter in Benares the weather was very cold, especially during the lunar eclipse and all the cases of eclampsia admitted to the Ishwaria Memorial Hospital were of a severe type. In December there were three cases treated by the routine morphine and chloroform method; these were all fatal. In January I resolved to try one of the newer methods of treatment for this disease.

Ten cases of eclampsia have been admitted up to date this year; nine were discharged in good health; one fatal case had repeated injections, presumably of morphine, before coming to hospital. The cases which received only magnesium sulphate with occasionally some chloral hydrate and potassium bromide in saline were all remarkably free from lung complications, and in spite of inadequate nursing attention did well. Rectal medication was given up in the later cases, because it was found that owing to restlessness patients did not retain the rectal catheters, and there were not enough nurses to allow of constant attention. As a rule patients were given castor oil or black draught as soon as they were able to swallow, and then also large doses of alkalies were given four hourly. Consciousness was usually complete on the third day post partum, and headache was complained of for a few days after this. No pituitrin was used in any stage of the labour. All the cases had been vaginally examined before admission and all had a febrile puerperium and for this reason many had to be kept a long time in hospital. The progress of

(Continued from previous page)

immunizing value of the anti-meningococcus prophylactic vaccine at this stage.

[Note.—A paper reporting the incidence of 27 cases of cerebro-spinal fever in the Borstal Institute during 1932-33 was published in our May number this year. There was little evidence then that the disease was being imported from outside, the carrier rate amongst new entrants being only 0.65 per cent. In 1934 the total carrier rate was only 1 per cent, but it is important to know what was the rate amongst new entrants only. If it was no higher than it was in 1932, we suggest that the main source of infection is within the institution.

The results obtained with the prophylactic vaccine, though not conclusive evidence, suggest that this measure may be successful in checking the epidemic; otherwise, the position appears to be serious enough to warrant more energetic measures. The searching for carriers amongst so-called 'contacts' only is not likely to effect much in the way of checking an air-borne epidemic.—EDITOR, I. M. G.]

labour was investigated only by rectal examinations after admission. The preparation of magnesium sulphate used was that prepared by the Bengal Chemical Company.

My house surgeons, Mrs. Mahadavan and Miss Deshpande, deserve my gratitude for their help and the interest they took in these cases.

Case 1.—Mohammedan, aged about 18 years, primipara, was admitted on 5th January, 1935, at 5-30 p.m. with a history of having had numerous fits since 10 a.m.

Findings.—Is in labour. Blood pressure—systolic 150 mm.; urine—albumin + + +.

At 6-30 p.m. an intravenous injection of 20 c.cm. of a 25 per cent solution of magnesium sulphate was given; as fits continued, the injection was repeated at 7-30 p.m. and from 8-30 p.m. a 2 c.cm. injection of the 25 per cent solution was given intramuscularly every hour up to midnight when fits ceased.

6th January at 8 a.m.—The membranes were ruptured artificially. During the day there were no fits, patient was deeply unconscious.

At 5-30 p.m. pulse was feeble and rapid so an intravenous injection of strophanthin, grain 1/100, was given.

7th January at 7 a.m.—A dead full-term foetus was delivered naturally, the placenta followed in 5 minutes, there was no post-partum hæmorrhage. The patient remained semi-conscious for 4 days.

1st February.—The urine was free from albumin for the first time since admission.

She was discharged on the 25th day post partum, her general condition being good.

Case 2.—Hindu, aged about 22 years, third para, was admitted on 15th January, 1935, at 5 p.m. in a state of deep unconsciousness, with a history of repeated fits since 11 a.m.

Blood pressure—systolic 170 mm.; temperature—100°F.; pulse—120; respirations—30; urine—reaction acid; albumin + + +.

At 5-15 p.m. an intravenous injection of 10 c.cm. of 50 per cent solution of magnesium sulphate was given, and repeated at 6-15 p.m. After the second injection there were no more fits.

At 8-15 p.m. a dead foetus was born naturally; placenta followed in 5 minutes; there was a slight post-partum hæmorrhage.

17th January.—The patient was completely conscious for the first time.

27th January.—There was only a trace of albumin in the urine.

2nd February.—The patient was discharged well.

Case 3.—Hindu, primipara, aged 19 years, was admitted on 18th January, 1935, at 10 a.m. with a history of 8 fits since 4 a.m. The patient was screaming on admission and had a fit as soon as she was put on the examination table.

At 10-30 a.m. a 12 c.cm. intravenous injection of a 25 per cent magnesium sulphate solution was given, and repeated at 11-30 a.m. after which there were no more fits.

20th January.—A stillborn foetus of seven months was delivered by breech.

6th February.—No albumin was present in the urine and the patient was discharged in good condition.

Case 4.—A primipara was admitted on 18th January, 1935, at 5 p.m. with a history of repeated fits from 7 p.m. the evening before.

Deeply unconscious.

Urine—albumin + + +.

She had a fit on admission; immediately on admission an intravenous injection of 10 c.cm. of 25 per cent solution of magnesium sulphate was given.

At 9 p.m. a stillborn foetus was delivered naturally.

19th January.—Fits recurred at 6 a.m. A 10 c.cm. intravenous injection of a 25 per cent solution of magnesium sulphate was given, after which there were no more fits.

27th January.—No albumin was present in urine.

21st March.—The patient was discharged well.

Case 5.—A primipara, aged 18 years, was admitted on 18th January, 1935, at 6 p.m. with a history of albumin in the urine and œdema of face and feet for some days; she had two fits before coming to hospital. Fits recurred on the examination table.

Urine—albumin + + +.

She was found to be in labour with foetal head un-fixed and pelvic measurements generally small. Cæsarean section was advised but relatives refused permission.

Ten cubic centimetres of 50 per cent solution of magnesium sulphate was given intravenously. There were no more fits.

19th January.—With high Kjilland forceps a live child was delivered which lived only 6 hours.

Patient's urine contained albumin till mid-February. She developed a pyelitis which cleared up after repeated injections of urotropin.

11th March.—She was discharged in fair condition but with a high degree of anæmia.

Case 6.—Hindu, aged 30 years, primipara, was admitted on 23rd January, 1935, at 12-30 p.m. with a history of numerous fits at home.

Urine—albumin + + + +.

An 8 c.cm. intravenous injection of 25 per cent solution of magnesium sulphate was given at 12-40 p.m. and repeated two hourly for 5 doses as patient had numerous fits.

Normal saline per rectum with 30 grains each of chloral hydrate and potassium hydrate to the point was given by the drip method. Digitalin grain 1/100 was given hypodermically every 4 hours for 48 hours.

24th January.—By midday the patient was having strong labour pains and was unconscious. External conjugate was 6 inches, foetal head did not fix. At 5 p.m. lower segment Cæsarean section was done and a living male child was delivered. The baby lived one month.

11th February.—Urine was free from albumin. The patient developed post-operative pneumonia, then a stitch abscess, and later had very bad diarrhoea for several days.

11th March.—She was discharged fit.

Case 7.—Hindu, aged 22 years, primipara, was admitted on 30th January, 1935, at 3 p.m. with a history of repeated fits since 3 a.m. and said to be in labour for 3 days.

Eight cubic centimetres of 25 per cent solution magnesium sulphate was given intravenously on admission.

The head was found to be on the perineum and a stillborn male foetus was delivered by low forceps. There was very free post-partum hæmorrhage which was controlled by hot saline intra-uterine douches and hypodermic injection of ergotinine citrate, grain 1/100, after expression of the placenta. Rectal drip of normal saline with potassium bromide and chloral hydrate of each grains 30 to the pint was given on return to the wards.

1st February.—The patient was conscious and had had no more fits since delivery.

4th February.—Systolic blood pressure was 100 mm.; the patient had had a secondary hæmorrhage which appeared to come from a cervical laceration; it was controlled by packing with glycerine gauze.

1st March.—Urine—free from albumin and the patient was discharged in good condition.

Case 8.—Mohammedan, aged 16, primipara, was admitted on 31st January, 1935, at 10 a.m. with a history of fits since 7 a.m. and in labour for 24 hours.

Urine—albumin + + + +.

Ten cubic centimetres of 50 per cent solution of magnesium sulphate was given intravenously at 10-30 a.m. and repeated at 12-30 p.m., 4-30 p.m. and 7 p.m. because of numerous fits during day.

Baby born naturally at 5-30 p.m.; living male—weight 9 pounds.

7th March.—Urine free from albumin.

(Continued at foot of next column).

ON THE ESTIMATION OF MINUTE QUANTITIES OF ATEBRIN IN THE BLOOD

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

A. C. ROY, M.Sc.

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

In a previous paper Chopra, Ganguli and Roy (1935) have shown that in monkey malaria there is no direct relationship between the concentration of quinine in the blood and the parasite count at any particular time. The highest concentration of the alkaloid attainable without producing marked toxic effects produces neither apparent reduction in the number of parasites nor degenerative changes in them. On the other hand, in the majority of cases there is a definite apparent increase in the number of parasites per c.mm. of blood after administration of quinine. The action of quinine on these parasites according to these workers does not appear to be direct, but probably synergistic to other mechanisms set up in the body.

We thought it would be of value to study the action of atebrian on similar lines and to make a comparative study of the action of these two drugs in this respect. The chief difficulty encountered was that there is no recognized method for the estimation of atebrian in the blood. We

(Continued from previous column)

17th March.—Discharged in good health—baby weighed only 5½ pounds on discharge.

Case 9.—Hindu, aged 17 years, primipara, was admitted on 13th March, 1935, at 4 a.m. with a history of fits for 2 hours, and in labour for 12 hours; an injection of morphine—strength not stated—given outside.

Urine—albumin + + + +.

At 4-30 a.m. 20 c.cm. of 25 per cent solution of magnesium sulphate was given intravenously.

At 5-20 a.m. a living male child delivered naturally. Fits recurred immediately after delivery so a further 10 c.cm. of a 50 per cent solution of magnesium sulphate was given intravenously.

14th March.—Fits began again at 6-15 a.m. Five intravenous injections each 10 c.cm. of 50 per cent solution of magnesium sulphate given during the day at two-hourly intervals to check the fits. Last injection was at 3-30 p.m. after which there were no more fits.

14th April.—The patient was discharged. Urine was free from albumin. The baby's condition was poor as the mother did not look after it properly.

Case 10.—Mohammedan, aged 17 years, primipara, was admitted on 6th April, 1935, at 6 p.m. with a history of fits since 7 a.m., and having had injections of morphine outside.

She had a fit on admission and was very restless. Temperature—101.8°F.; pulse—128; respirations—40 per minute.

Eight cubic centimetres of 50 per cent solution of magnesium sulphate was given intravenously, after which there were no more fits.

7th April.—Patient deeply unconscious; foetal heart sounds not present, foetal head low in pelvis so cranioclast was applied without chloroform and foetus slowly extracted. The patient never regained consciousness.

9th April.—Patient died, apparently of pulmonary œdema.

had therefore to evolve a suitable method for this purpose. As atebtrin is a base, which is easily soluble in ether and which behaves in most respects like an alkaloid, we thought that the method which was employed for quinine estimation might be applicable to the estimation of atebtrin also.

As a result of some preliminary experiments regarding the solubility of the atebtrin base and its salts, it was observed that atebtrin was not soluble in acidified zinc sulphate solution nor in saturated ammonium sulphate solution as is the case with quinine, but the base is extremely soluble in amyl alcohol. When the extracted atebtrin is dissolved in dilute acids alone, the gradation of colour developed after the addition of Roy's reagent (1926), or potassium bismuth iodide reagent as recommended by Vedder and Masen (1931), is not sharp enough for delicate comparisons. It was also observed that the extraction of atebtrin with ether is more complete when the filter paper strips in which the blood has been soaked are dried in an electric oven at a temperature of 50°C. for about an hour. After a number of trial experiments, the following procedure was found to give fairly accurate results :—

Oxalated blood containing known amounts of atebtrin was allowed to soak into the strips of filter paper contained in the inner tube of Vedder and Masen's apparatus (1931) as modified by Chopra, Roy and Das Gupta (1934). It was then put inside an electric oven at a temperature of 50°C. for about an hour. The filter paper strips were reshuffled by means of a clean platinum loop. A small pledget of cotton was placed in the mouth of the tube, which was then inserted into the outer jacket. Ether was poured through the top of the inner tube, so that after filling it up, it was allowed to overflow and fill nearly half the bulb portion of the outer tube. This was then connected to a reflux condenser through which cold water was allowed to circulate and it was immersed in a hot water bath up to the level of the ether contained in the outer tube. After the extraction had been allowed to proceed for two hours, the inner tube was removed and the ether extract contained in the outer tube was heated to drive away the ether. The extracted atebtrin was dissolved in 4 c.cm. of N/10 HCl by alternate heating in a boiling water bath and shaking. As the atebtrin is mixed up with the extracted fatty materials of the blood it usually takes several minutes to get it completely into solution. This is then well cooled in ice and filtered through a small Whatman filter paper. Three cubic centimetres are now accurately measured into one of a set of small test tubes of uniform bore and all made of the same kind of colourless glass tubing and to the others varying amounts of the standard atebtrin hydrochloride solution in N/10 HCl were added. The standard atebtrin solution used contained 0.01 mg. of atebtrin hydro-

chloride per 1 c.cm. of the solution. The total volume in each tube was made up to 3 c.cm. by the addition of varying amounts of N/10 HCl. 0.1 c.cm. of 20 per cent caustic soda solution was next added to each tube followed by 1 c.cm. of amyl alcohol and then thoroughly mixed. The test tubes were left for some time on the table to allow the amyl alcohol layer to separate completely. The yellow colour of the solutions was completely taken up by the layer of amyl alcohol and in the standards the intensity of coloration was proportional to their respective atebtrin contents. The colour of the amyl alcohol layer in the unknown was compared with that in the standards against a white background, the tubes being looked through sidewise.

Experiments with known amounts of atebtrin gave fairly satisfactory results as will be seen from the following table:

	Atebrin hydrochloride added in mgm.	Atebrin hydrochloride recovered in mgm.
1	0.025	0.022
2	0.020	0.016
3	0.020	0.018
4	0.015	0.012
5	0.005	0.005

As solutions of atebtrin exhibit remarkable fluorescence when exposed to ultraviolet light and as the intensity of fluorescence was found to depend upon the atebtrin content, we thought that by this means we might be able to detect minute differences in the atebtrin contents of solutions. But while this holds good for standard solutions of atebtrin (a difference of 0.001 mgm. can be readily detected) it is otherwise when atebtrin extracted from blood is compared with the standard solutions. It was found that ethereal extracts of blood unmixed with atebtrin, when treated in the manner described before, exhibited an appreciable fluorescence when exposed to the ultraviolet lamp and moreover the nature of this fluorescence was not the same as with the standard solutions.

As all attempts to intensify the colour of the atebtrin solutions failed and as the use of the various alkaloidal reagents did not give any better results we employed the device of concentrating the yellow colour of atebtrin into a small volume of amyl alcohol and then making the comparisons.

Summary and conclusion

A simple and fairly accurate method of estimating minute quantities of atebtrin in the blood has been described.

UNUSUAL IDENTIFICATION OF EXPLOSIVE

By N. J. VAZIFDAR, L.M. & S., F.C.S., F.C.P.S.
CAPTAIN, A.I.R.O.

*Acting Chemical Analyst to Government of Bombay,
and Professor of Forensic Medicine, Grant Medical
College, Bombay*

On the 26th March, 1935, about 12-30 a.m., an explosion occurred in a garage at Bomhay and a man was found lying severely injured.

He was brought to the Sir J. J. Hospital at about 1-30 a.m. with severe multiple injuries including a penetrating wound of the abdomen and lacerated left hand with fingers blown off.

He was operated upon at 4-15 a.m., the abdominal wound explored and several pieces of porcelain taken out; similar pieces were also recovered from the wound in the right wrist and his left hand had to be amputated.

On the same day the police sent me the following articles for examination and detection of any explosive substance:—

- (a) A torn blood-stained warm singlet.
- (b) A torn blood-stained cotton singlet.
- (c) A circular metal screw-on lid of a jar with some white powder and pieces of china stained yellow.
- (d) Fragments of china stained yellow.
- (e) Two human finger tips with nails and a piece of skin.

In all exhibits I detected chlorate of potassium and sulphide of arsenic, which forms a highly explosive mixture, a fulminate, and it was apparently in a porcelain jar with a metal screw-on lid.

In my opinion while the man was screwing on the lid, some fragments of the powder remaining outside on the threads of the jar exploded on account of the friction and the man was injured.

Symons has described under the heading 'Unusual Identification of Explosive' a case in which three persons were injured in an explosion which occurred at Colombo in December 1932 where some crackers consisting of chlorate of potassium and sulphide of arsenic exploded accidentally. He found arsenic in the urine of all the three patients collected on 20th December, five days after the explosion. Symons deserves great credit for his ingenuity in tracing the nature of explosive by examination of the urine of the victims.

As this was the only case so far recorded I requested the police to have the urine of this man collected. This was done on 1st April, full six days after the explosion, and 1/250 grain of arsenic was detected by me by Gutzeit's test.

On the 20th April the patient developed dermatitis and on the 29th hair and nail parings were sent to me for examination. Arsenic in the quantity of 1/125 grain was again detected.

Finding of arsenic after a few days is of no unusual interest as after a single dose arsenic is found in the urine within half an hour and continues to be excreted for about ten to fourteen days. Of course when arsenic is given in repeated doses it is found for much longer periods.

Arsenic has indeed been found in the urine of a person 111 days after a course of seven injections of neosalvarsan and even fifteen months after a course of ten injections of novarsenohenzole.

In such an explosion as the one under discussion arsenic enters the system through the wound and also by inhalation of arsenuretted hydrogen which is evolved in the explosion.

This case is of unusual medico-legal importance in that the finding of arsenic would form a very important link in the chain of evidence in proving that in a suspect the injury on his body was caused by the explosion of a mixture containing chlorate of potassium and sulphide of arsenic, which is often used in bombs.

Chlorate of potassium will also form an explosive mixture with sulphur and this mixture is commonly used in India in the manufacture of crackers but in that case no arsenic can be found in the urine of the injured. The finding of arsenic in the body of the victim thus gives an important clue as to the nature of the explosive used and so far as the records go this Bombay case is only the second case of this nature to be reported and it is the first of its kind in India.

A Mirror of Hospital Practice

A CASE OF PSOAS ABSCESS TREATED WITH INJECTIONS OF MILK

By A. C. ROY

Charitable Dispensary, Midnapore

Psoas abscess is generally chronic in nature and secondary to tuberculous disease of the lumbar vertebra but acute psoas abscess is not rare. The following is the report of a case recently seen by me:—

In the middle of November 1934, I was called in to see a case, a Hindu male, aged 45, for a swelling in the left side of the abdomen—duration six weeks.

Previous history.—The patient is a settlement surveyor and he had to work in the field, standing all day long. He had felt some pain in the groin, and in the evening on coming home he used to notice an enlargement of the testes but, after a night's rest, the testes returned to their original size. The patient cannot definitely say which of the testes had enlarged. This happened for two to three years and after that there was no trouble.

Present history.—Early in October 1934 the patient had to go to a place about twenty-five miles away on foot and returned again on foot two or three days later. Four days later he went to a place on foot about eight miles away from his residence and in the afternoon

when he had finished his work he felt a pain in the groin. He lay down for a couple of hours to take some rest thinking that the pain might become easier in the meantime. It may be mentioned that he had not walked such long distances for nearly twenty years. The pain gradually increased and he decided to go home on foot in spite of the pain. After walking about a mile he was unable to walk any further and he had to lie down on the road-side and wait for a passing motor car. While waiting on the road-side he felt a pulsating or throbbing sensation in the left side of the abdomen. He also felt some pain in the testes and in half an hour he was attacked with fever which came on with rigor.

After coming home by car he was given some homœopathic medicine and, on the application of soap over the abdomen, the bowels moved twice in the night. Next morning there was no fever and one testis was found to be double its normal size. There was no pain. He had fever for seven days with daily intermissions. After that he had no rise of temperature. The testes gradually diminished in size and a swelling on the left side of the abdomen was noticed after five to six days. There was some increase in the size of the swelling at odd times. There was no trouble with urine or bowels.

The case was first seen by me in the middle of November 1934 and on examination the following were found:—

Fullness and perceptible bulging of the abdomen was noticed on the left side. The skin over the front of the abdomen on the left side and the skin on the back from the left iliac crest upwards were slightly cedematous. Patient was lying at ease and did not look at all ill.

On palpation a globular swelling about the size of a tennis ball was found in the left iliac fossa occupying the centre of the inguinal ligament. The swelling was hard, hot and slightly painful on deep pressure. The mass was fixed and not movable in any direction. Palpation was suggestive of a deep-seated abscess with pus inside the mass. It was dull to percussion.

There was no difficulty in straightening the leg. There was no pain and he had no difficulty in standing. Evidence of spinal disease could not be detected. Movements of the hip joint were quite free and painless.

The right testis was found to be slightly larger than the left one which was normal in size. There was nothing special about the other systems.

A leucocyte count was not done.

A diagnosis of an abscess was made but the patient did not like to take any medicine for the present.

About five weeks later I was again called in to see the case in December 1934. The swelling was still present and the skin was cedematous as before. This time I decided to explore the abscess with a hypodermic syringe and needle, and so satisfy myself as to the correctness of my diagnosis. I was not even allowed to do this however, leaving aside the question of an operation.

Without satisfying myself as to the correctness of my diagnosis I decided to put the man on an iodide mixture and give him a few injections of milk. He was put on the iodide mixture for nearly three weeks and six bi-weekly injections of fat-free sterile milk were given starting from 5 c.cm. gradually rising up to 10 c.cm. After each injection up to the third there was gradual diminution in the size of the mass which was reduced to one-fourth its original size while it became soft in consistency and the patient felt a little better. He was then asked to walk in the courtyard for five to ten minutes and after walking for a couple of days the mass regained its original size. The remaining injections were given but there was only a slight diminution in the size of the mass although the patient improved in health. The iodide was stopped after the sixth injection and he was given a general tonic internally for nearly three weeks. The mass then began to subside gradually and, from the middle of February 1935, no trace could be found of it even on

deep palpation. Up to the time of writing the mass has not reappeared and the patient is quite all right. He is now carrying on his usual work without any trouble or discomfort. It may therefore be surmised from the absence of any symptoms or reappearance of the mass for the last ten weeks that the case has been cured without any operative interference.

Discussion.—It will be seen that the diagnosis of an abscess was made from (1) the presence of a swelling in the iliac fossa, (2) cedematous condition of the skin suggesting inflammation underneath, (3) palpation suggesting deep-seated pus and (4) from the presence of a hot painful mass.

The diagnosis could not be confirmed by an exploratory puncture.

The other interesting points to note in this are:—

(1) No fever throughout except for the first seven days.

(2) No pain.

(3) No flexion of the hip.

(4) No difficulty in walking even when the swelling was present.

(5) Legs could be straightened without any pain.

The usual operative treatment was not adopted and the patient was treated with injections of milk and iodide internally. It is now very difficult to find out what brought about the cure of the condition. Was it cured by injections of milk or spontaneously by the gradual absorption of the pus formed underneath? or was the absorption hastened by the leucocytosis brought about by the injections of milk? The latter is probably the cause of the cure of the condition as the abscess was not absorbed in three months prior to the injections while the condition was cured following the treatment.

[Note.—It is not clear to us how a definite diagnosis of psoas abscess was arrived at.—Editor, I. M. G.]

A CASE OF SPONTANEOUS SUBARACHNOID HÆMORRHAGE IN AN OLD MAN

By M. ABDUL HAMEED, M.D., M.R.C.P.

King George's Medical College, Lucknow

A. G., aged 60 years, father of ten children, went to stool on the morning of the 23rd November, 1934. While there, he suffered severe pain in the back of his head and became unconscious. He regained consciousness after ten minutes and complained of a pain in the back. On the second day the pain in the head and the back became much less. On the third day he again had a severe headache followed by a convulsion which soon passed off. For the next five days, pain in the head and back persisted though not very severe and the patient remained walking about and continued rubbing his back with some liniment.

On the night of the 1st December, 1934 (ninth day of disease), the headache again increased and was followed by some temporary unconsciousness. The next morning the headache was much worse and he felt as if the head was going to burst, as a result of which the patient started crying out and vomited several times. Soon after this he became drowsy, which lasted for twelve hours. The doctor who saw the case at that time found paresis in the left arm and slight proptosis of the eyelids. His

blood pressure was then recorded as 210/110. On regaining consciousness he complained of pain in the head and the back, from where it radiated to the legs as well.

Next morning I was asked to see the case and found him less drowsy and more restless. He was then complaining of pain in the head, neck and back going down to the legs. Rigidity of the neck was present. Pain in the nape of the neck on deep pressure was also elicited. Kernig's sign was present. There was no paresis. Knee, ankle, biceps and triceps jerks were present; abdominal reflexes were also present. Plantar reflex was normal. Pupils reacted sluggishly and were equal. A hæmic bruit was present in the heart. Temperature 101°F ., pulse 78 per minute, blood pressure 170/90. A diagnosis of spontaneous subarachnoid hæmorrhage was suggested. Lumbar puncture was done and blood-stained fluid came out under pressure. On keeping the fluid in a test tube for some time, the red blood cells settled down in a very small number and the supernatant fluid became clear but showed deep xanthochromia. There was no spontaneous coagulation of the fluid. Albumin in the fluid 0.25 per cent, chlorides 0.85 per cent and urea 0.19 per cent; culture, sterile; Wassermann reaction, completely negative; van den Bergh reaction, indirect positive.

The patient was put on bromides and calcium lactate by mouth and he passed a better night. Next morning, drowsiness and restlessness continued and he complained of less headache and less pain in the back. The reflexes with the exception of the abdominal had disappeared. Rigidity in the neck persisted. The blood pressure was as high as before and pulse 72 per minute. Three days later he became more restless; temperature went up to 103.4°F .; blood pressure, 200; pulse, 80 per minute; reflexes, absent. Lumbar puncture at this stage was refused. During the next three days he became more and more restless and delirious; the blood pressure had now a tendency to fall; the pulse and temperature were rising. Another lumbar puncture was done and it showed blood-stained cerebro-spinal fluid under pressure, but the colour of the fluid was not so high as on the previous occasion. Next day he became more deeply unconscious, and his pulse and respiration failed, resulting in his death. No post-mortem examination was allowed.

The typical history of severe headache followed by pain in the back accompanied later on with rigidity of the neck and tenderness of the nape of the neck led me to think that he had some intracranial hæmorrhage, probably subarachnoid. Meningitis could be ruled out on account of the peculiar onset of the symptoms. Cerebral apoplexy is also not considered possible because of the insidious onset and long course of the illness. The typical cerebro-spinal fluid with slight increase in the amount of protein and with van den Bergh indirect positive confirmed the diagnosis that hæmorrhage had taken place somewhere under the arachnoid.

The above case conforms with the 'lumbago and sciatica syndrome' described by Professor Arthur Hall in connection with the different manifestations of spontaneous subarachnoid hæmorrhage and impresses on us the importance which should now be attached to cases of lumbago, especially when they are either accompanied with or preceded by severe headache or migraine. A lumbar puncture in such cases

may help in warding off a fatal issue in a certain number of patients.

As regards the pathogenesis of this condition, it is supposed to be due to leakage from and subsequent rupture of a 'berry aneurysm' situated on a vessel of the brain especially the basilar artery and the circle of Willis. Leaving out trauma, neoplastic growths and the infective processes, such aneurysmal dilatations may be due to three different pathologico-ætiological groups:—

1. Arterio-sclerotic—due to degenerative condition of the vessels.
2. Syphilitic (rare).
3. Congenital.

Out of the above three groups, the first is usually met with in the young adult life, the second one in the middle life, while the third is found among the old. There may be some exceptions to the above rules. The case quoted above was an old man and hence the chances were that he had a degenerative condition of the vessels at the base of the brain. The hæmorrhage was due to an arterio-sclerotic aneurysm probably on the basilar artery. A condition of general arterio-sclerosis was further suggested by the increased amounts of chloride and urea in the cerebro-spinal fluid. I consider the basilar artery the most probable site because aneurysm situated above that area would almost certainly show definite localizing signs, which were absent in this case.

A CASE OF SEPTICÆMIC PLAGUE SIMULATING PERNICIOUS MALARIA

By H. A. YENIKOMSHIAN, M.D., D.T.M. & H., M.R.C.P.
Associate Professor of Medicine, American University of Beirut

PLAGUE is sporadic in Beirut. During autumn and winter we see more cases, and occasionally we get a scare of an epidemic. But during the spring and summer the number of cases diminish. I have no satisfactory knowledge about the rodents and fleas of the country to explain this phenomenon. The following case is quite unusual in Beirut and of sufficient interest to warrant publication:

A school girl, twelve years of age, was admitted to the American University of Beirut Hospitals in a state of coma on the 4th of March 1933. She was in perfect health on the 2nd of March. On that day she woke up with a sore throat and vomited bilious fluid twice. At noon her mother was frightened to find that she could not wake up the child. A doctor was called who found that she was in a state of light coma, responding only to painful stimuli, and had high fever. She lives in a malarial district, has a large, hard, spleen and has had malaria, lasting for two months, several years previously. The doctor gave her an injection of quinoplasmine. She had an attack of convulsions during the night, and the next day she was brought to this hospital.

The state of coma, that she was in on admission, simulated a cerebral form of pernicious malaria.

Physical examination.—Well developed, fairly well nourished, temperature 40.5°C. (105°F.), pulse 120, respiration 28 per minute.

Face congested, no rigidity in the neck. Only slight redness in the throat.

Pupils equal and react to light.

No apparent disease in the chest.

Liver palpable, spleen hard and reaches three fingers below the costal arch.

No glandular enlargement.

LABORATORY EXAMINATIONS

Blood count.—Leucocytes 13,700, polymorphonuclears 82 per cent, lymphocytes 6 per cent, large mononuclears 11 per cent and eosinophils 1 per cent.

No malarial parasites found. Several smears were examined.

Urine.—Albumin ++, acetone ++, microscopic examination—many granular casts.

Lumbar puncture obtained clear fluid, which did not come under high tension and showed no pathological changes.

Blood sugar 80 mgm./100 c.cm.

Urea N 50 mgm./100 c.cm.

Chlorides 370 mgm./100 c.cm.

Diagnosis was not clear. We had no cases, at that time, of cerebro-spinal fever or epidemic encephalitis in Beirut. The patient was not diabetic and had no history of chronic kidney disease. Comparatively high blood urea nitrogen in the presence of low blood chlorides could be explained by dehydration due to vomiting and starvation. Apparently this was an acute infection with cerebral involvement. A blood culture was taken, also a throat swab. Her acidosis and dehydration was treated by intravenous glucose and saline, and despite the absence of malarial parasites in the peripheral blood, diagnosis of pernicious malaria was entertained and she was treated by injections of quinine and plasmochin.

Next morning the patient seemed to be much better. The temperature came down to 37.8°C. (99°F.), she could retain some food in the stomach, and could speak intelligently. In the afternoon of the same day she had another rise of temperature and vomited, the vomitus containing dark blood, went into coma again, the temperature rose, the coma got deeper and deeper, and she died at midnight of that day with a temperature of 42°C. (107°F.).

Another blood count made on that day was:

Leucocytes 18,000, polymorphonuclears 72 per cent, mononuclears 24 per cent, lymphocytes 3 per cent, and eosinophils 1 per cent.

As no autopsy was permitted we made a splenic puncture after death and found bi-polar staining oval bacilli, morphologically similar to the plague bacillus. On the same day the laboratory reported that her blood culture showed a growth of a short non-motile Gram-negative bacilli, suggestive of *Bacillus pestis*. This was confirmed by inoculating the culture into a white mouse and rubbing the same on the shaved skin of a guinea-pig. The mouse died three days after inoculation, and the guinea-pig after eight days. On autopsy of these animals, typical *Bacillus pestis* were obtained.

Dr. G. C. Low (Price, 1930) describes a cerebral form of plague which clinically resembles very closely cerebral pernicious malaria. In my case there was a high mononucleosis—11 per cent and 24 per cent—and moderate leucocytosis. Though we have examined many smears, Leishman stain, for plasmodium malaria, we have seen no organisms suggesting *Bacillus pestis*.

AN INTRACTABLE ULCER ON THE SCALP

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
and

L. M. GHOSH, M.P. (Cal.), D.T.M.

(From the Calcutta School of Tropical Medicine,
Medical Mycology Inquiry under the Indian Research
Fund Association)

A boy aged 14 years came to the outpatient department with an ulcer about one and a half inches in diameter on the top of his head.

Previous history.—About three years ago the boy had a continued fever lasting for about six weeks. This was very severe and during its course he had convulsions and was delirious. Towards the end of this pyrexial attack the lobes of the ears, the alar nose and the scalp on the vertex became 'black' (probably gangrenous). One day he scratched his scalp and the whole of it came away over an area about six and a half by four and a half inches, leaving the skull exposed. The ears and nose gradually recovered and appear to have healed without any scarring. The large exposed area on the scalp also gradually lessened and in about six months there was a granulating ulcer about one and a half inches in diameter which was surrounded by a ring of dense scar tissue of the already-healed portion.

Various treatments were tried for a period of about two years without any permanent benefit, though at times the ulcer diminished in size, but it always broke down again and reached its former dimensions. On one occasion a skin graft was done in another hospital and after about six months he was discharged with the ulcer reduced to about one-third of an inch in diameter, but it very soon broke down again.

Before treatment.

Condition on coming to the School.—There was a superficial ulcer on the top of the head covered with unhealthy indolent granulations. The margins showed no signs of healing and the blood supply was poor on account of the ulcer being completely surrounded by a dense ring of scar tissue about two inches in width.

Cultures from the pus only produced ordinary pyogenic organisms, the Wassermann reaction was negative, and the boy appeared otherwise healthy; the only other abnormal condition present was a hookworm infection of moderate severity.

Treatment.—At first the boy was treated as an out-patient; 1/5,000 acriflavine lotion was applied during the day and one per cent ammoniated mercury ointment at night, and at the same time ultra-violet ray treatment was given twice a week. After six exposures had been given there was no improvement and so the boy was admitted to hospital.

After treatment.

The ulcer was treated with simple boracic fomentations three times a day and the exuberant granulations were touched with pure silver nitrate washed off immediately with normal saline. A careful watch was kept and whenever the granulation tissue rose above the surface it was reduced with silver nitrate; this was needed about twice a week.

At the same time muscle extract (Saccolan) was given in doses of 1 c.c.m. injected twice weekly.

The hookworm infection was also eradicated with oil of chenopodium. The ulcer was definitely smaller, the granulations were not so exuberant and the skin edge had a healthy healing border, but improvement was exceedingly slow.

Two per cent scarlet red ointment was now applied at night, the healing edge being protected from it with boro-vaseline ointment, and during the day boric fomentations were continued, and about once a week the granulations were touched with silver nitrate. Muscle extract injections were now only given once a week. After about four weeks of this modified treatment the ulcer had completely healed and the boy was discharged.

Over two months later there was no sign of the skin breaking down so the patient may be regarded as cured.

A CASE OF CYSTICERCOSIS

By J. R. DOGRA, M.D.

CAPTAIN, I.M.S.

and

D. M. AHERN

LIEUTENANT, R.A.M.C.

(From the District Laboratory, Razmak)

A BRITISH soldier, aged 24, was admitted to hospital on 31st March, 1935, complaining of 'fits'.

Past history.—The patient has 8½ years' service in India. In 1931 he was admitted to hospital for pneumonia and was treated for tapeworm during convalescence. He states that at Bareilly he had his first 'fit' while playing football. This was attributed to cardiac irritability of adolescence. Ever since he has suffered from headaches and breathlessness.

On admission.—He has had two 'fits' since admission. One of these came on during examination in the ward. The patient felt a cramp in his left hand which went into a spasm in the *main d'accoucheur* position. He was fully conscious and realized that an attack was coming. A few seconds later his whole body was in tonic spasm and consciousness was lost. He frothed at the mouth with stertorous breathing and deep cyanosis, dilated pupils and head and eyes turned to the right. Knee jerks were absent. The spasm was not violent and passed off and the patient awoke after five minutes but remained drowsy for some four hours. He had no evacuation of urine or faeces.

The patient's general health is good; his intelligence is normal; smokes and drinks very moderately.

During the past 3 or 4 years he has noticed several little lumps in his skin, which disappear in 3 to 4 months. One of these was removed from the pectoral region. It was a cyst—*Cysticercus cellulosae*—with a beautifully invaginated scolex and neck.

Nervous system revealed nothing abnormal. Cardiovascular system revealed mitral systolic murmur which was not conducted and did not alter on exertion. X-ray examination showed no enlargement of the heart. The murmur can be explained by imagining a cyst in the region of the mitral valve. Blood pressure was 140/80.

X-ray examination of the skull and limbs, etc., showed the presence of calcified cysts.

Examination of the faeces was negative for ova. Blood examination showed absence of eosinophilia. The cerebro-spinal fluid was not under pressure, was sterile on culture, and showed presence of sugar but excess of proteins. Wassermann negative.

Conclusion.—A case of 'fits' due to tæniasis is recorded. The great importance of x-ray examination in all cases of 'fits' is pointed out. Removal and subsequent examination of the cyst is not often possible.

Absence of eosinophilia and ova in the faeces was noted by MacArthur (*Medical Annual*, 1934, page 168).

We wish to thank Lieut.-Colonel G. R. Lynn, Officer Commanding, C. I. M. Hospital, Razmak, for permission to investigate the case.

Indian Medical Gazette

SEPTEMBER

EPIDEMIC DROPSY

EPIDEMIC DROPSY was first recognized as a separate clinical entity about sixty years ago. During the intervening years a number of epidemics—using the word in its widest sense and without, we hope, conveying any suggestion that the disease is necessarily an infectious one—of this disease have occurred; the epicentres of these outbreaks (perhaps a safer word) appear to have been in Calcutta, but this location may have been apparent only and due to this city being both the largest town and the largest medical centre in the province. Whenever an outbreak of any importance has occurred within the province, however, there have always been reports of the incidence of the disease in neighbouring provinces and in some instances in more distant countries; following one of the earliest recorded outbreaks in Calcutta there was an outbreak in Mauritius, and last year extensive outbreaks occurred in Benares in the United Provinces and in Assam, so that for this reason, as well as for others that we shall refer to later, epidemic dropsy is a disease of much more than purely local interest. In 1926 there was a sharp rise in the incidence curve, but the 1934 outbreak is probably the most serious that has yet occurred.

There is probably no disease that is attracting so much public attention in Bengal as is epidemic dropsy at the present moment. In the inter-epidemic periods the disease is of interest mainly to the medical investigator, but directly it assumes epidemic proportions there is a spate of the usual questions in the Legislative Council and the Corporation, and public meetings are called to discuss the problem. There is good reason for the alarm that is caused by this disease; it is not uncommonly a fatal one; it causes abortion in a large percentage of pregnant women attacked even when the other symptoms are mild; the frequency and severity of the eye complications alone are sufficient to make it a serious matter; the cardiac involvement often leaves the patient in a condition unfit to do any work during a long period of convalescence; it attacks whole families and, as rest is a very important part of the treatment, a domestic situation is created that is often hard to cope with; and, lastly, our lack of exact knowledge regarding its aetiology makes it impossible to adopt measures for the successful prevention of the disease. Ignorance as to the direction from which danger is coming adds very much to the fear experienced and is liable

to create a state of panic. Another reason why so much public attention is drawn to the disease is that the educated middle-class members of the community are amongst those most severely affected. For guidance, members of the general public naturally appeal to their medical practitioners and the official bodies to their sanitarians; neither are at present in a position to give a readily authoritative opinion on the subject, and both turn to the research worker for help.

Many theories regarding the cause of the disease have been formulated, have lived their day and become history, and have been revived again. It is a disease that seems to lend itself to theorizing on inadequate grounds, and there are probably few diseases about which so much unscientifically collected data and so many isolated observations supposed to have a bearing on the aetiology have been published. The medical literature in this country contains innumerable papers in which one or two cases are quoted proving or disproving, in the authors' opinions, some particular theory. Single instances can neither prove nor upset any theory. For example, the rice-toxin theory, which is probably the best established of the theories of the present day, is not upset by the fact that all the members of one family that have avoided rice for months suffer from clinical symptoms indistinguishable from those of epidemic dropsy. Rice may be the best pabulum for the production of the specific toxin, and yet there may still be other foodstuffs in which it can occur. On the other hand it cannot be assumed just because all the victims of an outbreak are rice eaters that rice is the cause of the disease.

The epidemiological investigations must be raised from the anecdotal to the scientific level. The population subjected to enquiries must be a large one and only selected on a geographical, not on an economic, social or religious, basis; the enquiries must be made amongst those who have not, as well as those who have, suffered from the disease; the mild cases of the disease must also be taken into account and this presents difficulties as it means that a careful medical examination of the whole population at the time of the outbreak is necessary; histories taken at a later date may be misleading. Very few investigations of this nature have been undertaken, but it is only through such investigations that we are likely to reach a solution of the problem.

The medical investigator into the aetiology of epidemic dropsy labours under many difficulties. In the first place he must face his task with an absolutely open mind; there are many theories and it is very likely that one will appeal to him more than another; impartiality is an essential quality in a good research worker. But he will have to depend for the collection of data on assistants who will all have their own theories which will almost certainly prejudice them in

the form their questions take, and lastly there are the patients themselves whose memories regarding recent events and whose answers to enquiries will undoubtedly be affected by popular prejudices. However, the greatest reactionary influence that the investigations have suffered has been the association of the disease with beri-beri and the actual use of the word 'beri-beri' instead of 'epidemic dropsy'. To us there seem to be practically no points of similarity, either in the symptomatology or the pathology, between the disease that is now rampant in Bengal and the beri-beri that has been claimed as the human counterpart of polyneuritis gallinarum of fowls. That in other countries certain epidemics which have been described as beri-beri bear a close relationship to our epidemic dropsy cannot be denied. But this is almost certainly because these have not been epidemics of classical beri-beri and are as distinct from it symptomatically, pathologically, and probably ætiologically as is our epidemic dropsy. In this respect the writers of textbooks might help us by dissociating the two diseases. In the present state of our knowledge there is more justification for placing epidemic dropsy amongst the bowel diseases than amongst the food deficiency diseases, but it would be more satisfactory and less likely to prejudice the issue if for the present it could be left in a section by itself or amongst diseases of uncertain ætiology. There seems little to be gained by emphasizing minor points of similarity between epidemic dropsy and even the 'wet' type of beri-beri that is seen associated with the classical 'dry' beri-beri in certain outbreaks of this disease. The differences in the pathology of the two diseases are so great that any similarity in symptoms may be looked upon as accidental and entirely superficial.

In this issue will be found a number of papers dealing mainly with the symptomatology and

pathology of epidemic dropsy. It was our original intention to publish other papers dealing with the ætiology of the disease but for various reasons these have not been included in the present number. However, the papers that we are publishing deal with the subjects of symptomatology and pathology from the general, the ophthalmological and the dermatological aspects in a fairly complete manner.

We shall be interested to hear from foreign workers who have had experience with the classical beri-beri whether they can detect any single point of similarity between the disease with which they are familiar and our Bengal epidemic dropsy, and we shall feel that one step towards the solution of the problem of the ætiology of epidemic dropsy will have been taken if it is once clearly fixed in the minds of those working on the problem that this syndrome has nothing whatsoever to do with the disease caused by vitamin B deficiency.

[It will be seen from some of the papers published in this issue that the workers at the Calcutta School of Tropical Medicine have been paying special attention to this important problem for many years. When the big epidemic occurred in Purulia during the winter of 1934 a field unit was organized in collaboration with the All-India Institute of Hygiene and Public Health and efforts were made to study this outbreak which was the first one involving rural areas on a large scale. Considerable spadework had already been done when in March 1935 the Governing Body of the Indian Research Fund Association gave a grant for the expansion and completion of this investigation. The problem is now being studied jointly by the two institutions from the clinical, the epidemiological, the bacteriological, and the biochemical standpoint with a view to working out the ætiology of the disease.]

Special Article

A NOTE ON THE USE OF SACCHARIN AS A SWEETENING AGENT FROM THE POINT OF VIEW OF PUBLIC HEALTH

By B. M. GUPTA, M.Sc., Ph.D. (Lond.), D.I.C.

*Deputy Public Analyst to Government,
United Provinces, Lucknow*

Introduction

AN examination of a large number of samples of sweetened aerated water indicates that saccharin is being extensively used as a sweetening agent in this country although this is not known to the majority of consumers. As saccharin is about 300 to 500 times sweeter than sugar, and the price is not proportionately higher, there is a great likelihood of this synthetic product being used to a larger extent in all articles of food and drink as a substitute for sugar. It is therefore of importance to

enquire into the possible toxicity of this coal-tar derivative and ascertain if it is desirable to restrict its consumption.

This question was raised in the House of Commons on 28th February, 1918. It was asked that, 'In view of the fact that the use of saccharin, saxin and the like preparations has now increased to a hitherto unprecedented degree and is likely to increase, will the Government obtain and make public the considered opinion of its advisers in the Department of Public Health as to their harmless or harmful character'. The reply given on behalf of the Government was that evidence is lacking: 'there is no foundation for the suggestion that saccharin as a sweetening agent is likely to prove injurious to health'. It was pointed out, at the same time, that a recent report of the Royal Society stated that evidence is lacking

as to whether saccharin is equally harmless to children. The conclusion seemed to be that sugar should be given to children, while saccharin may be quite safely taken in moderate quantities by healthy adults. Even at the present time there is no statutory rule in Great Britain restricting the use of saccharin, although it is possible for the Government to regulate its price by arrangement with the trade.

In Germany, by the laws of 1898 and 1902, saccharin and similar substances were discriminated against, and their manufacture and sale made unprofitable. Saccharin was treated as a poison; when used in foodstuffs it was legally an adulterant. War conditions caused the Government to consider saccharin, dulcin, etc., as aids in a time of need and the enforcement of the law was suspended. During 1917 to 1919 about 1,000 tons of artificial sweetening agents replaced some 300,000 tons of sugar. Although no injurious effects on health could be traced to their use, the new law, promulgated after the war, has taken over almost all the repressive measures of the old law.

In the United States, Folin and Herter (1911) and others carried out extensive investigations, from which it appears that

- (1) saccharin, after prolonged administration, acts as a chronic irritant to the stomach,
- (2) saccharin causes an increased secretion of hydrochloric acid in the stomach, the sweetening effect being lost after a time and the patients taking a dislike to it.

It was also argued that as a sweetener in canned foods and preserves it is a deception, the public believing saccharin to be a form of sugar. The sale of saccharin has therefore been prohibited by law in the United States, and Food Inspection Decisions (nos. 135 and 138) notified that 'the Secretary of Agriculture will regard as adulterated under the Food and Drugs Act foods containing saccharin which on or after 1st January, 1912, are manufactured or offered for sale in the District of Columbia, or Territories or shipped in interstate or foreign commerce or offered for importation in the United States of America'.

The use of saccharin in beverages and prepared foods of various kinds and as a sweetening agent in proprietary medicines has also been prohibited in several European countries.

Chemical and pharmacological properties.—Saccharin is the anhydride of ortho-sulphamido-

benzoic acid $\text{C}_6\text{H}_4 \begin{smallmatrix} \nearrow \text{SO}_2 \\ \searrow \text{CO} \end{smallmatrix} \text{NH}$ and is also

known as glusidum. Commercial saccharin often contains less than 50 per cent of actual glusidum. It is a light, white, minute crystalline powder. One part of saccharin dissolves in 400 parts of cold water, 24 parts of boiling

water, 500 parts of chloroform, 25 parts of 90 per cent alcohol and 48 parts of glycerine. It unites with alkaline carbonates evolving carbon dioxide from the latter and yielding soluble saccharin, which is equally sweet. As a sweetening agent in diabetes, glusidum is used in the proportion of 1 part in 10,000 and $\frac{1}{2}$ grain (30 mgm.) takes the place of an ordinary lump of sugar. Cuslins considers saccharin to be innocuous. Solis-Cohen and Githens (1928) are of opinion that, as it is unnecessary in the management of diabetics and other persons to whom sugar must be prohibited, it should not, on account of possible ill effects, be prescribed for them nor used in medicinal preparations.

Verschaffett (1915) found that the toxicity of sodium saccharinate to seeds and parts of plants is less than that of sodium benzoate ($\text{C}_6\text{H}_5\text{CO.ONa}$) or benzamide ($\text{C}_6\text{H}_5\text{CO.NH}_2$) but greater than the disodium salt of sulpho-benzoic acid ($\text{SO}_3\text{NaC}_6\text{H}_4\text{CO.ONa}$) or sodium phenylsulphonate [$\text{C}_6\text{H}_5(\text{OH}).\text{SO}_3\text{Na.2H}_2\text{O}$]. In 1917 Best studied the action of saccharin on the gastric digestion, and found that in customary doses saccharin is harmless. Blodgett (1920) carried out experiments in which two men and one dog were fed with varied amounts of saccharin over long periods of time, from which no deleterious results were observable, thus leading to the opinion that the use of saccharin by diabetics is harmless. Katsumi Haramaki (1922) studied the influence of saccharin on certain functions of the digestive tract and kidneys, and found that large doses of saccharin increase gastric secretion in dogs, small doses do not influence urinary secretion but 20 per cent causes diminution in urinary output for a time. Benjean (1922), studying the influence of saccharin solutions on fish life, germinations of seeds, enzyme actions and on dog and man, came to the conclusion that the acidity of saccharin is likely to affect these processes and that failure to take into account the acid function is responsible for disagreement in the literature. He is further of opinion that saccharin is harmless in doses permitted by taste. Miyadera (1922) fed a dog with 0.4 gm. of saccharin per kilogramme of body weight and found that this amount has no effect upon N-balance over a period of seven days. Heitler (1920) thinks that the use of saccharin for sweetening purposes should be entirely forbidden on account of its depressing action on the heart. Heilmann (1922) reports that a boy 9 years of age ate 200 saccharin tablets or 3.5 gm. of saccharin; there was delirium, loss of consciousness for a short time, hallucination, motor disturbance, and an enormous urticaria with big blisters containing coagulated serum; recovery was rapid. It is argued that the transitory character of the symptoms induced by the massive doses is a proof of its harmlessness in ordinary use. Van Eweyk (1922) studied the influence of saccharin on the heart

and circulation and found that it has no demonstrable influence in doses much larger than can be given by mouth. Fantus and Hektoen (1923) found that rats may be fed on saccharin in relatively enormous amounts without producing lesions and that such feeding does not interfere with the development of the animals or their progeny or shorten their lives. Schwarz and Buchlmann (1924) found that neither saccharin nor its sodium salt (crystallose) nor p-saccharin inhibits the diastatic action of saliva. Even in concentration of 1.25 per cent an inhibitory action is doubtful. Schwarz and Zelinger (1924) found that peptic and tryptic digestion as determined by the Full-Gross method is not inhibited by saccharin, its sodium salt nor p-saccharin, even in concentrations far beyond those employed for sweetening purposes. Uglow (1924) finds that saccharin has a marked bactericidal action, better than that of phenols and similar to that of salicylic acid. It injures enzymes, phenols and 'zooplankton'. The sodium salt has nearly the same effect as saccharin itself, which this author regards as a poison. Dobreff (1925) studying the effect of the constant use of saccharin upon the digestive juices could not observe any functional disturbance of the stomach glands. Neumann (1924) is of opinion that, in spite of the poisonous effect of saccharin on lower forms of life, the amounts ordinarily used in food had no harmful effect, and caused no appreciable decrease in the percentage utilization of proteins. Lehmann (1929) found that the administration of large amounts of saccharin to mice for three generations appeared to have no effect upon their growth, development, or ability to reproduce. Bleyer and Fischler (1931) studied the effect of saccharin on bio-catalysers and metabolic processes, and could not observe any injurious effect on the influence of vitamins from feeding saccharin. Diemair and Fischler (1931) found that in a rabbit weighing 1 to 1.5 kilogrammes daily doses of saccharin of 25 to 50 mgm. do not affect the blood-sugar level nor the liver glycogen content.

A warning against the indiscriminate use of saccharin was issued by Ross (1915). He stated that 'Recent researches at the McFadden Laboratories of the Lister Institute has shown that saccharin is a powerful auxetic like several other constituents and derivatives of coal-tar; and there is now strong evidence that it is these auxetics in tar and pitch that give rise to the predisposition to the epithelioma known as pitch and sweep's cancer. Saccharin, therefore, should be taken internally with caution, and not for long periods unless the patient is suffering from diabetes or other really serious complaint'. Although this statement does not seem to have been contradicted in any medical journal it appears from a private communication that the suggestion that saccharin may predispose to cancer is not accepted by the present

authorities of the Lister Institute and the Cancer Hospital in London.

Carlson, Eldridge, Martin and Foran (1923), after carrying out an extensive investigation on the physiological action of saccharin in the Hull physiological laboratory of the University of Chicago, summarize the results as follows:—

'1. The prevailing view that, except for its action on the organs of taste in the mouth, saccharin is an inert substance, having no action on organs and tissues, is not tenable. Saccharin acting in the mouth decreases appetite and gastric secretion; in the stomach it increases gastric secretion, and decreases peptic digestion; in the small intestine it decreases absorption; acting on the erythrocytes it decreases hæmolysis. These actions of saccharin cannot be explained by the osmotic factor.

2. Saccharin in the blood, in proportion to its concentration, passes into the lymph, cerebro-spinal fluid, saliva, tears and mammary secretion'.

Summary

A careful consideration of the above investigations will show that saccharin is not an acute poison, and that a daily ingestion of small quantities of saccharin for several months by healthy adults does not seem to produce any injury. It has no food value, and in large doses it may cause headache, gastro-intestinal disturbances and mental depression. If saccharin is freely permitted to be substituted for sugar, it will be taken by old and young, in all states of health, and for all time. There is at present no evidence to establish the claim that saccharin even in very small quantities so taken is harmless. It is therefore suggested

- (1) That the sale of food and drink containing saccharin and similar products should be brought under control, and
- (2) that effective steps be taken so that nobody may unknowingly take these synthetic coal-tar derivatives.

EPIDEMIC DROPSY DISCUSSIONS AT THE BRITISH MEDICAL ASSOCIATION: CALCUTTA BRANCH

UNDER the auspices of the Calcutta Branch of the British Medical Association discussions on epidemic dropsy were held at the lecture theatre of the Calcutta School of Tropical Medicine on Friday, the 14th December, 1934, and on Friday, the 11th January, 1935. On the first day of discussion there was a record attendance of the medical practitioners of the city, so much so that there was not even sitting accommodation available in the large lecture theatre.

On the first day, Lieutenant-Colonel A. D. Stewart, Director of the All-India Institute of Hygiene and Public Health and one of the vice-presidents of the branch, presided. The discussion was opened by Dr. U. P. Basu who traced the evolution of the ætiology of the disease and dealt with its treatment. He was followed by Dr. M. N. De who gave a lantern demonstration of coloured plates from the pathological findings and by Lieutenant-Colonel E. W. O'G. Kirwan, who described the ocular findings of this disease.*

Dr. U. P. Basu said: This disease first appeared in Calcutta in the winter seasons of 1877-78-79-80. In the same year it was imported to Assam and Mauritius by coolies who had gone there from Calcutta. The outbreak was limited to particular quarters of Calcutta and the death rate was high. The famous I. M. S. officer, Colonel Kenneth McLeod, who was at that time occupying the chair of clinical surgery at the Calcutta Medical College, thought that it was a disease *sui generis*, and noted that in this disease the nerve symptoms were completely absent. He was of opinion that it was a different clinical entity from beri-beri and gave it the name 'epidemic dropsy', as the two leading manifestations were its epidemic nature and the presence of dropsy. Indeed no better name could be given and during the half century that has elapsed since McLeod's time there have been vigorous attempts by eminent scientists to merge this disease into beri-beri, but McLeod's 'epidemic dropsy' has outlived all criticisms, and stands to-day recognized as a special disease.

The second outbreak occurred in Calcutta in 1901. This was small and affected a few houses only. The next severe epidemic occurred in Calcutta between 1907 and 1909 and began in July. It rapidly spread from Calcutta to Howrah and thence to the neighbouring districts of Bengal. Lieutenant-Colonel E. D. W. Greig made a special study of this disease and thought that it was a deficiency disease resembling ship beri-beri. The late Sir Pardey Lukis who was at that time principal of the Calcutta Medical College held that it was a form of angioneurosis. Simultaneously Sir John Megaw studied Anglo-Indian cases in the Presidency General Hospital and concluded that it was a form of beri-beri and the cause lay in a poison which was developed in the rice during the hot and rainy season

by micro-organisms. While the I. M. S. officers were searching for the cause of this disease the independent medical profession of Calcutta was not sitting idle. The late Dr. Satya Saran Mitra, an eminent physician of the city, studied the disease in Howrah and came to the conclusion that the cause of the disease was adulterated—mustard oil. He supported his theory by observing that the Europeans and Marwaris do not suffer from this disease as they do not take mustard oil. About the same time Rai Bahadur Dr. Hari Nath Ghose, another distinguished city physician, thought that the epidemic was due to infection of rice by a fungus which probably changed the protein constituents of rice into a product like histamine which was the cause of vaso-dilatation and local œdema. He published his observations in the *Calcutta Medical Journal* in 1909 and 1910.

Since 1910 numerous small outbreaks have occurred in Calcutta, Howrah and in other districts of Bengal from time to time. In 1925 Lieutenant-Colonels Acton and Chopra confirmed Sir John Megaw's view that epidemic dropsy and beri-beri are different clinical aspects of a toxic syndrome caused by the ingestion of poisonous bases formed in the rice by a spore-forming proteolytic bacillus of the *Bacillus vulgatus* group. They further observed that hypoadrenia in particular and hypothyroidism to a lesser extent increased the susceptibility. Then came the largest epidemic of 1926. When the city was in the grip of the fearful epidemic in October 1926 the independent medical practitioners of Calcutta met at a conference at the Calcutta Medical Club to discuss the nature of the outbreak. Dr. U. P. Basu remarked at the conference that epidemic dropsy was altogether a different disease from beri-beri. It was neither due to avitaminosis nor to poisonous bases formed in rice, but that the dramatic outbreaks of this disease in large epidemics, accompanied with fever, having a clean-cut clinical picture, pointed to some acute infection being at the bottom of this disease (vide *Calcutta Medical Journal*, October 1926). In 1927 Acton and Chopra further investigated the disease and held that the œdema was due to capillary dilatation giving rise to increased transudation of fluid into the tissues. Sections of the skin showed increased vascularity in the subpapillary vascular plexus, the vessels were easily seen and round them there was an exudation of lymphocytes and epithelial cells. Side by side with this vascularity there was œdema which separated the white and elastic tissue fibres of the corium. The enormous increase of vascularity of the subcutaneous fatty tissue and the dilated vessels suggested nevoid tissues. In September 1932 a further discussion was held amongst the independent practitioners of this city at the Calcutta Medical Club in which Dr. U. P. Basu stressed the infective origin of this disease on account of its sudden onset, short incubation period, early prostration and the presence of fever. He suggested that at least in the severe types it was very probably a streptococcal infection manifested by progressive anæmia, troublesome diarrhoea, and a tendency to hæmorrhages, such as epistaxis, hæmatemesis, metrorrhagia, bleeding piles and even hæmorrhagic retinitis. In some of these cases the clinical picture was that of

* These two papers will be found elsewhere in this number.

septicæmia. Dr. Basu believed neither in the rice-intoxication theory nor in the adulterated mustard oil theory, because he was convinced that many well-authenticated cases of this disease could be collected where the disease broke out among the members of a particular household, or among the inmates of a particular room in a mess, when a patient infected with the disease was admitted to that particular house or room, although the source of rice supply remained the same immediately before and during the outbreak of the disease. In 1934 another epidemic broke out and instead of being limited to Bengal as before it spread to many healthy towns of Behar and the United Provinces. In Benares the disease has affected the Bengalis severely, but not the other rice-eating communities, although the source of rice supply to the Bengalis and non-Bengalis remains the same. The rainy season has always been invoked in the ætiology of this disease in order to establish the deterioration of rice due to damp storage, but the first appearance of the disease was in the winter months of the year 1877. Again in 1922 there were 83 inches of rainfall in the city of Calcutta and the whole of the district of Kidderpore was flooded but epidemic dropsy never broke out in that year. The vitamin deficiency theory has already been explored, nor can the adulterated vegetable ghee theory hold place in the ætiology of this disease, because unimpeachable evidence is available that it is rampant in families which consume the best foodstuff available in the market.

Of all theories of intoxication the one propounded by Rai Bahadur Hari Nath Ghose, namely, that of histamine poisoning, appeared to be reasonable, as it explained to a great extent the pathological lesions seen in this disease, but the great drawback of this theory is that it did not explain the dropsy that is present, which is its cardinal feature. According to Samson Wright, Professor of Applied Physiology in the University of London, œdema of the tissues that can be demonstrated by pitting on pressure is not evident in histamine poisoning. Schlittenhelm and Schlecht investigated an outbreak of œdema in the labour corps attached to the German army and proved that protein starvation was at the root of the epidemic œdema. We have also seen that administration of proteid food materially benefits the condition. The question therefore naturally arises in one's mind, is epidemic dropsy due to infection on the top of hypalbuminosis of the blood serum? The question cannot be answered unless the protein content of the blood serum is investigated in a large number of cases. Study of the biochemistry of this disease has shown deficiency in the calcium content of the blood serum. It is worth while to study the cholesterol content of the blood, as Cannon, after two years' research in Hongkong on 600 cases of beriberi with 80 necropsies, found low cholesterol content of the blood.

Treatment.—Whatever may be the ætiology of this disease, change of soil, especially change of climate, materially improves the condition. I have known desperate cases verging on death and carried by stretcher to health resorts markedly benefited simply by the change. No medical treatment was carried on in such cases, but rest in bed in healthy climates improved the condition. The next factor is the addition of animal protein to the diet. The addition of meat and eggs to the diet is certainly helpful, and the administration of calcium in any form is beneficial.

In 1930 Lieutenant-Colonel Chopra and Dr. U. P. Basu found out that the tincture of ephedra prepared from the Indian species, by virtue of its containing larger quantities of dextro-rotatory isomer pseudo-ephedra and comparatively less ephedra, possesses the property of stimulant action on the musculature of the arteries; a powerful stimulant action on the myocardium; the small quantity of ephedrine exerts its vaso-pressor effects through the vasomotor nerve endings and consequently stimulates the acceleratory mechanism. Our observations were confirmed by Lieutenant-Colonel E. H. Vere Hodge in his article in

the *Indian Medical Gazette* on this subject in November 1931 and by Lieutenant-Colonel Chopra himself and Dr. Sunil Chandra Bose in an article on the subject in the *Indian Medical Gazette* in November 1933.

On the second day of the discussion Dr. U. P. Basu, one of the vice-presidents of the branch, presided and many leading medical men took part in the discussion. Rai Bahadur Dr. Hari Nath Ghose opened the discussion and emphasized the probability of histamine intoxication as being at the root of the disease. Dr. Sarat Chandra Dutta of Howrah said that during the course of his practice extending over nearly half a century he had been a stalwart supporter of the rice theory but that with his advancing years and wider experience on the subject he did not think that rice has any place in the ætiology of this disease. Dr. E. Muir described his personal experience of an outbreak in Purulia in the district of Manbhum and emphasized the importance of deteriorated rice in the ætiology of this disease. Dr. Coltman of the Presidency General Hospital remarked that he studied the disease amongst the Anglo-Indians in the Presidency General Hospital in 1929 and came to the conclusion that it was of an infective origin; he quoted the findings of Major Shanks, the Professor of Pathology, Calcutta Medical College, who from post-mortem examinations in epidemic dropsy cases thought that the disease was caused by infection. He also quoted Lieutenant-Colonel Boyd who fed monkeys with samples of diseased rice said to have caused the disease but failed to produce the disease in them. Lieutenant-Colonel Kirwan next read a report of the chemical examination of fluid removed from the eyes of patients suffering from glaucoma seen in this disease. Dr. Muir asked Lieutenant-Colonel Kirwan if any control examination of fluids removed from normal eyes had been made. Dr. Basu then wound up the discussion by thanking the distinguished audience for the interest they had evinced and his colleagues who had taken part in the discussion for the new light that they had thrown on the matter. Dr. Basu confessed that up till now we have conceived many theories but have not succeeded in bringing to light anything. Lieutenant-Colonel Kirwan's isolation of histamine from the glaucoma fluids in these cases is a distinct advance on the subject. We all know that the symptoms of shock appearing after injury are due to the liberation of histamine from the tissues, so that, as Lieutenant-Colonel Kirwan has himself said, it remains to be seen whether the histamine isolated is primary or secondary. The difficulty however with histamine is that it cannot explain the œdema. [The president was interrupted by Rai Bahadur Hari Nath Ghose, an advocate of the histamine poisoning theory, who said that œdema was due to secondary infection on the top of histamine poisoning.] Replying to Dr. Muir, Dr. Basu said that the disease first broke out this year in a virulent form in Purulia and if infected rice were the cause why should this disease occur particularly this year and in an epidemic form. Could it be possible that the rice remained innocent all these years and suddenly deteriorated this year all over the place to produce an epidemic?

ALL-INDIA OPHTHALMOLOGICAL SOCIETY

As a result of the deliberations of the above Society at its Fourth Conference in Madras on the 22nd, 23rd and 24th April, 1935, at which the urgent need for more co-ordinated and energetic measures in connection with the prevention of blindness in India was emphasized, the Committee respectfully submit the following to the authorities concerned both in British India and the Indian States.

1. Before registration, certification of licensing of qualified medical practitioners, midwives, or others concerned with the conduction of child-birth, a guarantee be given by competent medical authority that aspirants for such registration, certification, or licence possess a practical knowledge of the prophylaxis of ophthalmia

neonatorum, preferably Crede's method or a modification thereof.

2. That in view of the very serious menace to sight constituted by that condition sometimes called xerosis of the conjunctiva or keratomalacia, but actually the expression of a multiple deficiency complex (a food problem), the authorities concerned, namely, the Government of India, the Indian Research Council and the Local Governments in British India and the various governments of the Indian States, do require of the special medical officers employed on nutritional research, a report on the human condition as seen in the hospitals, and practical suggestions as to how the food defects concerned may be met by alternative food crops or similar measures adopted in co-operation with the Agricultural Department or other departments concerned with this problem.

3. That the statements quoted from official sources by the International Association for the Prevention of Blindness in their report for 1934 on the frequency of trachoma in certain regiments of the Indian army is viewed with concern. Over 70 per cent of the Sikhs in certain North-West Frontier regiments are said to be affected. The percentage of infected Punjabis, Pathans and Dogras in these units is also very high. It is respectfully requested that the authorities under the Government of India responsible for these figures explain how they were arrived at, and what criteria, if any, were employed in making the diagnosis of trachoma. Should the figures be correct, then these regiments constitute a grave danger not only to the Indian army in time of war, but—more important to this society—a grave danger to the civil population of those districts to which such regiments may be transferred in time of peace. It is suggested that the authority concerned—in this case the Government of India—takes the necessary steps to institute an enquiry under competent specialist control to check the figures quoted, and to lay down rules of guidance regarding the diagnosis of trachoma.

4. That legislation regarding the inspection of the eyes of school children be introduced at a very early date by all the authorities concerned throughout British India and the Indian States.

5. That the authorities concerned tighten up the administration of the machinery dealing with the prevention of smallpox.

6. That the authorities concerned institute propaganda methods for the instruction of the uneducated with regard to the prevention of blindness, especially in the rural population.

Such methods, in the beginning, might consist of:—

(i) Broadcasting by radio in the vernacular where the necessary machinery is established.

(ii) Distribution of pamphlets and posters through the medical and educational departments.

(iii) The employment of a travelling motor unit organized for propaganda work fitted with cinema, posters and pamphlets, and a dispensary for urgent ophthalmic aid. This motor unit to be manned by a cine-operator and lecturer, and a qualified ophthalmologist, so that first aid may be given on the spot at the places of demonstration.

The films and posters used must be simple, topical and sufficiently colourful to arrest the eye, and as far as possible self-explanatory. Films should be on the lines of the health films used by the Rockefeller Foundation in India. Captions, if any, must be in the vernacular. The lecturer must understand and speak the vernacular, and be able to give a running commentary.

7. That, as syphilis, both congenital and acquired, is such a potent cause of blindness, the authorities concerned—the Local Governments in British India and the various governments of the Indian States—institute and foster—or extend if already in existence—the branch of their medical departments devoted to the treatment of venereal diseases. Such special departments should be modelled, in so far as possible, on the lines of similar departments already in existence in Great Britain.

CHETTINAD MEDICAL ASSOCIATION

THE usual monthly meeting of the above association was held at the S. M. Hospital, Tirupattoor, under the presidency of Dr. Mangalam Pillai, as the president was absent. About twenty members were present; after the tea arranged by the hosts, Dr. T. S. Shetty, the secretary, read the minutes of the association.

Dr. T. S. Shetty gave three interesting case reports, two of diphtheria cases, one in a child of three years, another in an adult of 35 years, both Indians. Curiously enough at the same time, one coming from Madura and the other from Ramnad district. Dr. F. Ysander cited two cases from his experience.

There was a discussion on the advisability of doing tracheotomy in advanced cases of breathing trouble. But Dr. F. Ysander suggested that intubation is a better method and easily done, but hospitalization is essential lest the tube be coughed out. Dr. Shetty spoke about a very interesting case of cerebellar abscess in a case of neglected mastoid infection.

Dr. Victor reported on two orbital tumours. Dr. F. Ysander demonstrated some interesting x-ray films of the gastro-intestinal tract. After this an interesting lecture on 'record keeping' was delivered by Dr. D. O. Sandel who suggested some novel and very easily manageable record-keeping methods for all outpatients, both in private and public institutions.

THE LEISHMAN MEMORIAL PRIZE

MAJOR H. T. FINDLAY, Royal Army Medical Corps, has been awarded the Leishman Memorial Prize for the year 1934, consisting of a silver medal and a sum of £30, for his work in the interests of military pathology.

The Leishman Prize (Officers) is awarded annually for the best piece of work in any branch of medicine, surgery or the allied sciences or in connection with the general duties of the Royal Army Medical Corps, by an officer of the Royal Army Medical Corps, or of the Army Dental Corps, or by an officer removed from either of these corps but still on the active list.

NORTH PERSIAN FORCES MEMORIAL MEDAL

CAPTAIN P. SHANNON, Indian Medical Service, has been awarded the North Persian Forces Memorial Medal for the year 1934 for his paper on 'A Study of Trachoma in Baluchistan' published in the *Indian Medical Gazette* of December 1934.

The North Persian Forces Memorial Medal is awarded annually for the best paper on tropical medicine or hygiene published in any journal during the preceding twelve months by a medical officer, of under twelve years' service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service, provided the memorial committee consider that any of the papers published has attained a standard of merit justifying an award.

THE ALEXANDER MEMORIAL PRIZE

MAJOR T. O. THOMPSON, Royal Army Medical Corps, has been awarded the Alexander Memorial Prize for the year 1934, consisting of a gold medal and a sum of £40, for his work in the interests of military hygiene.

The Alexander Memorial Prize is awarded annually to the officer of the Royal Army Medical Corps who has by professional work of outstanding merit done most to promote the study and improvement of military medicine, military surgery, military hygiene or military pathology.

CHARAK MEMORIAL PRIZE

A PRIZE of the value of one hundred rupees will be given for a thesis on the antiquity of syphilis (venereal diseases) in India.

The thesis should be in English. Short quotations from original references in Sanskrit or other languages will be accepted.

Complete bibliography of authors, facts and figures, and data of matter in the thesis should be given.

The thesis should be submitted, typed on one side only, on foolscap size paper with double spacing and margin on the left, and should not exceed fifty such pages. The manuscript should reach the editor, *Indian Journal of Venereal Diseases*, 94, 97, Girgaum Road, Bombay 4, by registered post, by the 30th December, 1935.

There is no territorial bar for competitors.

The thesis submitted will be judged by a small board of examiners.

The winning thesis will become the property of the *Indian Journal of Venereal Diseases*, and will be published in one of the issues. The journal will have its copyright.

No reason will be given for refusal or rejection of any or all the theses submitted. The decision of the editor shall be final on all matters.

An authoritative, literary and scholarly article will be appreciated.

RAI SHAMBHU DAYAL SAHIB GOLD MEDAL

A GOLD MEDAL called the 'Rai Shambhu Dayal Sahib Gold Medal' will be presented for the best prize essay on a public health subject to be announced each year.

The subject of the next essay is 'A practical scheme for rural reconstruction with special reference to matters pertaining to public health'.

The competition will be open to the general public, including the medical and the public health workers in the United Provinces.

The essay is to be written in Hindi and should not exceed 3,000 words in length.

Essays should reach the Medical Officer, Provincial Hygiene Institute, United Provinces, Lucknow, by 30th November, 1935.

The name and address of the competitor must be distinctly written on each essay submitted and the envelope should have the words 'Prize Essay' in the top left-hand corner.

The Director of Public Health, United Provinces, shall judge the merit of the essay and his decision with regard to the award of the medal shall be final. No correspondence will be entered into on the subject of competition. No essay will be returned.

WILLIAM GIBSON RESEARCH SCHOLARSHIP

With reference to the notice regarding the above scholarship for medical women which appeared in our December issue last year, we are informed that the council of the Royal Society of Medicine has awarded this scholarship to Dr. F. Stephen-Lewis of the University of the Witwatersrand, Johannesburg.

Dr. Stephen-Lewis proposes to carry out a research on 'Further study in the chemistry of South African plants, particularly those used by the natives as medicines', and 'Investigation of physiological data for the various native tribes'.

INDIAN MEDICAL COUNCIL

LIEUTENANT-COLONEL P. S. MILLS, M.B., B.S. (Lond.), D.T.M. & H. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., Officiating Inspector-General of Civil Hospitals, Bihar and Orissa, has been duly nominated by the Government of Bihar and Orissa, under clause (a) of sub-section (i) of Section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India, *vice* Colonel H. C. Buckley, I.M.S., resigned.

Lieutenant-Colonel N. S. Sodhi, M.C., L.R.C.P., L.R.C.S. (Edin.), L.R.F.P. & S. (Glas.), D.M.R.E. (Cantab.), D.T.M. (Edin.), L.M. (Dub.), I.M.S., Officiating Inspector-General of Civil Hospitals, Burma, has been duly nominated by the Government of Burma, under clause (a) of sub-section (i) of Section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India, *vice* Lieutenant-Colonel P. K. Tarapore, I.M.S. (retired), resigned.

Current Topics

The Treatment of Cerebro-spinal Fever

By J. M. KENNEDY, M.B., D.P.H.

Senior Medical Officer, Lodge Moor Hospital, Sheffield

(Abstracted from the *British Medical Journal*, 13th April, 1935, p. 756)

Diagnosis

THE disease presents no difficulty in those cases which show the classical signs of meningitis, such as headache, neck rigidity, and Kernig's sign, but it is in respect of those cases where the above signs are wanting that I wish to make a few remarks. I have found that in most infants of about 1 year and under a correct diagnosis can only be made after lumbar puncture. These cases merely showed the following features:

(a) A remittent type of temperature of about 102°F., for which no definite cause could be found.

(b) Irritability and restlessness, which became more marked in routine examination.

(c) Complete absence of neck rigidity, head retraction, and Kernig's sign.

(d) Several cases showed a very heavy and dull appearance of the eyes, with slow gyrate movement of the eyeball, to which latter sign I attached some importance.

Speaking of the symptomatology of cerebro-spinal fever, Mogilinski states:

'The onset in infants differs considerably from that in adults, in whom it is sudden and accompanied by

shivering, vomiting, high fever from the first, headache, rigidity of the neck and limbs and in most cases (60 to 70 per cent) herpes labialis. In infants, on the other hand, it is rare to find an onset accompanied by convulsions, high fever, and vomiting, but the disease usually begins insidiously, without meningeal symptoms or herpes. In some cases there may be signs of respiratory disease, followed later by meningeal symptoms'.

The fever seems to bear little or no relation to the severity of the symptoms, except immediately before death, when the temperature may reach hyperpyretic degrees—107°F. or over. The pulse appears to be as variable as the temperature when the patient is seen in the early days of the disease; it is usually soft, full, and slow. Often one sees a patient with a temperature of 102° and a pulse rate of 60. When the patient is restless and suffering much pain the pulse is usually small and rapid.

As regards the special symptoms—vomiting, headache, and rashes—about 98 per cent of patients give a history of vomiting in the first day or so of the disease, but it is not seen much in hospital when they are under treatment. Most of my patients complained of severe frontal headache during the early days of their illness. The large purpuric type of rash resembles that seen in an acute pyæmic infection, and appears rapidly. The prognosis is very grave. The other type of hæmorrhagic rash—the petechial variety—is not so likely to be fatal, and resembles the 'rose spot' of typhoid fever or fresh flea-bites. Herpes usually appears around the

mouth, but may occur in any part of the body, such as the hands, feet, legs, around the vulva, and the anus. The most characteristic point about the herpes is that it appears with unfailing regularity on the fourth day of the disease, and also that the contents of the vesicle contain the meningococcus.

Lumbar puncture as an aid to diagnosis

Too much stress cannot be laid on the value of lumbar puncture. I consider that it is a simple and harmless operation, and should be performed more often—especially during epidemics of cerebro-spinal fever—in those patients where the slightest suspicion arises. I have carried out over 1,500 lumbar punctures, and never have I seen any fatal results follow the operation. Lumbar puncture is one of the most valuable aids and means at our disposal for arriving at a correct diagnosis. The macroscopic appearance of the cerebro-spinal fluid usually gives a fair idea of the type of meningitis. Should it be the least turbid, anti-meningococcal serum should be given forthwith, without waiting for a bacteriological report. On the other hand, a clear fluid does not eliminate cerebro-spinal fever.

Present lines of treatment

In the treatment of cerebro-spinal fever I think it is generally agreed that the best results have followed the introduction of anti-meningococcal serum. When Flexner read his paper on the treatment of cerebro-spinal fever by the use of anti-meningococcal serum he gave the mortality rates in epidemics before serum was introduced or applied as follows: New York, 73 per cent; Edinburgh, 80 per cent; Glasgow, 74 per cent; Belfast, 70 per cent; France, 75 per cent; Belgium, 77 per cent; Palestine, 80 per cent.

He then showed a mortality of 30.9 per cent on 1,294 cases treated with anti-meningococcal serum.

When Flexner introduced his serum he advised the following method in the treatment:

A daily lumbar puncture and intrathecal injection of 30 c.cm. of serum for at least three or four days, in adults, with a proportionately smaller injection, if thought advisable, in infants. In more severe cases he considered that larger doses of serum should be given at even shorter intervals, say, every twelve hours, and that this treatment should be continued for as many days as were necessary to clear the cerebro-spinal fluid and to alleviate the symptoms of meningitis.

Since the introduction of serum many observers have differed as to the best route for its administration.

Herrick, believing that the disease originates as a generalized meningococcus sepsis, endeavours to sterilize the blood stream by massive doses of anti-meningococcal serum given intravenously. Banks states that it has been his practice to give large doses of multivalent serum—for example, an initial dose of 100 to 200 c.cm. intravenously—and to do repeated lumbar punctures at twenty-four-hour or forty-eight-hour intervals, with or without an initial intrathecal administration of serum.

Cantacuzène has published perhaps the best results ever known, and he has reduced his mortality rate as low as 4.8 per cent. In brief, serotherapy is administered as follows:

- (a) Intraspinal inoculation as early as possible.
- (b) Daily inoculation of 25 to 35 c.cm., the operation being always preceded by microscopical examination of the cerebro-spinal fluid, which should serve as a guide.
- (c) Stop the inoculations as soon as the meningococci have disappeared and the purulent character of the fluid is changed, otherwise there is a danger of serous meningitis.
- (d) Inoculate the serum as closely as possible to the infected site and in young children perform intraventricular injections through the fontanelle.
- (e) The intraspinal injections should be accompanied by intramuscular inoculations.

Personal experience

During the years 1931-2-3, 369 cases of cerebro-spinal fever were admitted into Lodge Moor Hospital,

Sheffield, of which 132 were fatal, giving a mortality rate of 33.06 per cent. Of these 132 deaths, fifty-two occurred within forty-eight hours of coming under treatment, which, when deducted, gives a mortality rate of 25.26 per cent. In 1931 there were eighty-five cases, with thirty-six deaths (42.35 per cent). In 1932 there were 160 cases, with forty-nine deaths (30.62 per cent). In 1933 there were 124 cases, with forty-seven deaths (37.9 per cent).

The following table shows the age incidence and death rate amongst the 369 cases during the three years:

Age	Cases	Deaths	Death rate, per cent
Under 1 year	25	15	60
1 year and under 5 years.	76	25	32.8
5 years and under 30 years.	218	67	30.7
30 years and over	50	25	50
TOTAL	369	132	33.06

During the year 1931 serum produced in Great Britain, France, and the United States of America was used, in the hope that we should find an efficient or active remedy, but it gave rather unsatisfactory and disappointing results. Towards the end of 1931 we were advised to try a serum produced in London. We used this serum exclusively for the treatment of our cases during the years 1931-2-3. By the results obtained during 1932-3 this serum would seem to have been very effective.

Of the 188 cases which recovered during 1932-3 by the use of this serum, I found that meningococci disappeared completely from the cerebro-spinal fluid after one intrathecal injection in ninety-eight cases, or 52.1 per cent, and that the meningococci disappeared in 148 cases, or 78.7 per cent, after having three consecutive intrathecal injections of serum. I believe that the presence or absence of the organism in the cerebro-spinal fluid is the only criterion by which we can form an opinion as to the value of the serum. I am inclined to agree with Dr. Cantacuzène that once the cerebro-spinal fluid has become sterile further intrathecal injections are dangerous, but it has been my practice to continue until the cerebro-spinal fluid has been found to be sterile on three consecutive days.

Out of the total of 132 deaths, the fifty-two occurring within forty-eight hours of admission to hospital were regarded as fulminating types of the disease. Of the remaining eighty deaths, it was found that in sixty-five instances (81.25 per cent) the cerebro-spinal fluid remained persistently positive in spite of daily intrathecal injections of serum.

It is my opinion that the intrathecal method is the best, and gives the most satisfactory results. I used this method in all cases, and in those cases which showed signs of a septicæmia (by the appearance of purpuric or petechial hæmorrhages) intravenous and intramuscular injections were used in addition.

We are informed that the cerebro-spinal fluid contains no complement, and thus no direct bactericidal action is likely to occur. The action of the serum is probably that of an increased phagocytosis. Physiologically, the lining membrane of the choroid plexus and the sub-arachnoid space is impermeable to substances passing from the blood to the cerebro-spinal fluid, except in the case of a few drugs. Serum injected intravenously must not reach the subarachnoid space, and, even if it does, must be in only very small and diluted quantities, and nothing like the amount which is brought into immediate and direct action by the intrathecal method.

I think that one can afford to neglect the clinical signs and symptoms that appear in the treatment of

cerebro-spinal fever, and to attach the greatest importance to the condition of the fluid, as to whether meningococci are present or absent. Rigidity and irritability are increased by the intrathecal injection of serum.

Some authorities advise cisternal puncture in the treatment of cerebro-spinal fever, but this method does not appear to me to have any advantage over the more simple lumbar puncture. It entails more risks, and should only be attempted by one skilled in the operation. By doing lumbar puncture one is able to drain the cerebro-spinal fluid very well and inject serum without any danger; the field of operation is quite safe, whereas in cisternal puncture the field of operation is exceedingly dangerous, and the injection of serum has to be done very cautiously. If one does not obtain cerebro-spinal fluid by lumbar puncture in patients suffering from cerebro-spinal fever, it is my experience that it will not be obtained by cisternal puncture, as the blockage usually occurs at the foramina of Luschka and Magendie, and has produced an internal hydrocephalus, so that the only thing that is of any value is ventricular puncture, which can be done quite easily in infants if the fontanelle is still patent.

Choice of anæsthetic

I prefer to do all lumbar punctures under a local anæsthetic, avoiding a general anæsthetic in all cases except those where a wildly delirious patient necessitates its use. In doing punctures under a local anæsthetic I give either morphine $\frac{1}{3}$ grain or heroin $\frac{1}{6}$ grain, according to the age of the patient, about a quarter of an hour beforehand, followed by 1 or 2 c.cm. of a 2 per cent solution of novocain. With a general anæsthetic, when the patient is coming round he is exceedingly irritable, noisy, and very restless, and even the subsequent administration of morphine or heroin has very little effect.

Death occurring during the acute stage of cerebro-spinal fever is usually brought about by respiratory failure. I have seen numerous cases in which this condition occurred, and artificial respiration was carried out for several hours while the heart continued to beat regularly and forcibly. Under general anæsthesia respiratory failure is more liable to occur, and this is another reason in favour of a local anæsthetic. Another point of interest may be mentioned here. The meningococcus is not so delicate an organism as is generally believed. As a routine, about 5 c.cm. of cerebro-spinal fluid was collected from the patient by punctures and run into a similar quantity of glucose broth. This was incubated overnight, and the following morning a tube was forwarded to Dr. Scott (of the Ministry of Health) by ordinary post, in most instances arriving quite safely. From a broth culture I inoculated a blood agar slope, which gave me a good growth. This was washed off with normal saline containing 0.5 per cent phenol, and an emulsion obtained, which I put up against the four standard sera and the type of organism identified. The typing of the meningococcus during an epidemic is exceedingly valuable, as the particular type is always kept in view, and any change that may occur in the types is recognized and, if necessary, the serum altered.

Conclusion

During an epidemic of cerebro-spinal fever, when a patient complains of headache, and has some pain or tenderness on flexing the head—not necessarily neck rigidity—the examination of the cerebro-spinal fluid should be carried out without further delay. One cannot stress too much the great importance of lumbar puncture in infants where there are no definite signs or symptoms of meningeal irritation other than pyrexia, with fretfulness or irritability. I am convinced that a number of infants die during an epidemic when the disease is not even suspected.

During an epidemic serum should be prepared at once from the type of organism causing the disease,

and freshly isolated strains of the infecting organism should be sent at regular and frequent intervals to the manufacturers of the serum. Once the disease is diagnosed, or when a turbid cerebro-spinal fluid is obtained, some anti-meningococcal serum should immediately be given intrathecally, without awaiting a bacteriological report on the fluid.

In treating the disease the condition of the cerebro-spinal fluid is very important, and as soon as it becomes sterile further punctures and injections of serum must be carefully considered. It has been my practice to obtain three consecutive sterile fluids before stopping the injections, though after I have obtained the first sterile fluid I reduce the quantity of serum. I believe that we do more harm than good by continued drainage of the cerebro-spinal fluid and intrathecal injection of serum. The examination of a direct smear is not sufficient evidence of persistent infection; the fluid must be cultured before it can be said to be sterile. Frequently the rigidity is increased by the intrathecal injection of serum, and no great importance need be attached to this, provided that the cerebro-spinal fluid is sterile on culturing.

In conclusion, I do not claim that my results are any better than those of other workers, but I think I can safely state that the quantity of serum used and the number of lumbar punctures performed are much less and that the number of days the patient is under active treatment has been reduced.

Uretero-vaginal Fistula

By A. E. WEBB-JOHNSON, C.B.E., D.S.O., F.R.C.S. (Eng.)
(From the *Lancet*, 11th May, 1935, Vol. I, p. 1083)

It would be difficult to exaggerate the terrible discomfort which a woman must suffer if she has a constant leakage from the vagina as the result of a fistulous communication with the urinary tract. The external genital anatomy of women provides no such convenient arrangement as that with which men are blessed, and the instrument maker has failed to produce an apparatus which will ensure a woman's comfort when she is suffering from urinary incontinence. It follows that she is generally dependent on primitive arrangements in order to absorb the leaking urine and save her clothes and the furniture of herself and her friends from damage. In addition to the discomfort which necessarily results—and this must amount to mental agony in a fastidious woman—the constant presence of a pad soaked in urine, which is often infected, sometimes leads to most distressing soreness of the genitals and thighs.

The surgeon is naturally distressed when he sees a patient in such a miserable predicament, but his distress is magnified a hundredfold when the state of misery is the result of an operation which has been embarked upon with confidence and hope.

The justification for confining my remarks to uretero-vaginal fistula lies in the fact that during the last 23 years I have had to deal with 23 of these cases, and have arrived at certain conclusions as to the best line of procedure in preventing and treating the condition. As I have stated, this serious condition is generally the direct result of surgical intervention. All my cases except one have been the result of a pelvic operation. In the odd one, which was the first I had to deal with, the fistula developed after a difficult parturition, protracted labour, and instrumental delivery.

Injury to the ureter: its prevention and repair

Before considering the question of treatment it will be well to devote a little time to the discussion of the prevention of injury to the ureters and the steps to be taken at the time if the surgeon realizes that damage has been done. The uterus, bladder, and lower ends of the ureters are in such close relationship, and the normal anatomical arrangement may be so distorted when the uterus is the site of a tumour, that it is not surprising that the ureter is injured sometimes.

Hysterectomy is so frequently performed that one may say that the ureters are in danger almost daily in the hospitals of a large city. Accidental damage still occurs too frequently, and it should be the guiding principle of the gynaecologist that it ought never to occur. In cases of fibroid tumour of the uterus the accident may happen without being noticed, but in Wertheim's operation for carcinoma, in the course of which the ureters are isolated, and maybe their blood supply imperilled, the surgeon is well aware of the risk being run and has the ureters under his direct observation. In a case of carcinoma it might be impossible to avoid damaging a ureter, but in the operation of hysterectomy for fibroids it should be one of the rarest of all accidents instead of one which is fairly common.

Twenty-one years ago Sir John Bland-Sutton opened a discussion on this subject at the Medical Society of London and the discussion made it clear that the ureters were often injured during the performance of abdominal hysterectomy. The injury may not be noticed. Bland-Sutton expressed the opinion that it is possible and probable that a ureter has been tied in the course of hysterectomy and the patient has recovered without anyone having a suspicion that such an accident has happened. It is indeed true that there may be no serious effect if the urinary tract is free from infection, but it is well to bear in mind that it may be some time before interference with the lumen of the ureters is revealed. I have recently had in my wards a case of nephrectomy for pyonephrosis in a woman who had a pelvic operation three and a half years ago. I doubt not that the obstruction to the ureter which was one inch from the vesical orifice was the result of the pelvic operation. While nephrectomy is never undertaken without the most careful investigation of the urinary tract, surgeons must be doubly cautious if the patient has had a pelvic operation.

The ureter has been deliberately tied after accidental division without untoward signs. Numerous gynaecologists have confessed to tying the ureter and dropping it back. This has only to be mentioned to be condemned. Bland-Sutton emphasized the importance of dealing with a cut ureter at the time. As he wittily pointed out—'Kidney tissue is very precious. Many persons get on very well in the world with very little brains and some with none, but no one can live without a certain amount of kidney'.

CHOICE OF PROCEDURE

There are various alternatives open to the surgeon when faced with this accident, and it is very desirable that a surgeon who is exposed to the risk of injuring the ureter should be prepared at once to repair the damage. He may attempt end-to-end union or he may graft the ureter into the bladder or into the colon. This last procedure would only be permissible if the injury were high up and a portion of the ureter had been removed. Fortunately, the injury when it occurs is nearly always quite near the vesical end of the ureter. End-to-end union is far from satisfactory. Only when the conditions are very favourable can a satisfactory union be made between the divided ends of the ureter. Moreover, should any narrowing occur it would not be so easily recognized or corrected as in the case of a graft into the bladder. I do not hesitate to say that the surgeon's duty is to implant the divided end of the ureter into the bladder. Great care is required in the performance of this operation, for if plenty of room is not left for the implanted ureter it may become sclerosed by chronic ureteritis which may narrow and even obliterate its lumen. The narrowing may be a gradual process and the obstruction to the ureter may lead to serious hydronephrosis or pyonephrosis after an interval of years.

This risk of narrowing can be avoided or minimized by careful attention to detail. In the first place a useful little manoeuvre is to pass long fine forceps along the urethra and make them protrude on to a selected spot on the posterior wall of the bladder. A small incision

is made on to the end of the forceps and the ureter drawn into the bladder by a thread which has been attached to it. The ureter can then be sutured to the bladder wall outside and a water-tight junction established. This method of grafting is not so certain of success as making the junction from inside the bladder. The surgeon need not hesitate to open the bladder during the course of an intraperitoneal operation.

If the bladder is opened and the ureter stitched in place from inside the viscus plenty of room can be left for the graft by leaving a gap below the suture line and passing a small drainage-tube through the posterior wall of the bladder into the retro-vesical tissues. The site of entry of the graft on the outside of the bladder can then be made extraperitoneal by suturing the pelvic peritoneum carefully over it.

If the bladder is not opened at the time and the implantation of the proximal end of the ureter is completed from outside the bladder the graft must generally be so closely sutured in position in order to make the junction absolutely water-tight that it is liable to become narrowed. If the implantation has been carried out in this way the graft should be kept under observation for some months and the opening of the ureter examined at intervals through a cystoscope. In this way any threatened contraction of the orifice, with the danger of damage to the kidney by obstruction and consequent increased risk of infection, can be recognized and dealt with either by dilating the orifice or, if necessary, by opening the bladder and improving the graft.

The surgeon may be labouring under the handicap that he is reluctant to call attention to the accident, but the interests of the patient demand that the graft should be kept under observation, and therefore the position must be faced and explained.

Treatment of uretero-vaginal fistula

I now pass to a discussion of the treatment of uretero-vaginal fistula. This may develop if the ureter has been cut and the injury has not been repaired, or if the blood supply of the ureter has been so interfered with as to lead to sloughing of the lower end, or if the ureter or part of it has been included in a ligature or suture.

When it is noticed that there is a leakage of urine from a vagina the surgeon has first to ascertain from what part of the urinary tract the leakage is taking place.

First of all he must satisfy himself that the urine is not coming from the bladder. This is not so easy as one might expect. By careful observation and by the injection of coloured fluids into the bladder and ascertaining if any of the fluid finds its way into the vagina this point is however eventually cleared up. Being satisfied that the leakage is not from the bladder the surgeon must next ascertain from which ureter the urine is escaping. Fortunately he may easily get a very helpful clue to guide him in this investigation, for cystoscopy and the passage of a ureteral catheter may soon reveal the side on which the injury has been inflicted. The injured ureter is always obstructed whether it be completely divided or not. There is always obstruction to the passage of a catheter on the side of the fistula if it has been present a few weeks. This clue generally leads quickly to a definite diagnosis in cases following hysterectomy for fibroids, but in cases following Wertheim's operation the position is complicated by the fact that both ureters have been so disturbed and are embedded in such dense scar tissue on the floor of the pelvis that it is often difficult to pass a catheter into either ureter.

Eventually however—perhaps only after several attempts and with the use of very rigid ureteral catheters or bougies, reinforced with metal—a passage is found up one ureter while the other is found to be impassable. The side on which the obstructed ureter is found indicates the side on which the fistula is present.

In spite of the difficulties we may have to contend with in order to be absolutely sure on which side the lesion is situated, we are indeed fortunate compared with our forbears. A reference to Sir Henry Morris's Hunterian lectures delivered at the Royal College of Surgeons a short 36 years ago makes one realize the great advantages under which we work to-day. At that time it was computed that in any hundred hysterectomies, vaginal and abdominal, one or both ureters were tied or cut across in at least three. And Spencer Wells in 1881 stated that out of 94 published abdominal hysterectomies one ureter had been divided in six, and both ureters in two other cases. For these injuries nephrectomy was performed and in many instances healthy kidneys were removed. It would be bad enough to be misled as to the injured side at the present day and to proceed to expose the wrong ureter, but how tragic it must have been in the days of which Morris spoke, when nephrectomy was the accepted remedy and there were not the same facilities for diagnosis that we possess to-day.

In speaking of the difficulties experienced by surgeons trying to identify the kidney which was in connection with the fistula Morris reported the following case:—

'A woman who had undergone vaginal hysterectomy by a distinguished gynaecologist recovered with an uretero-vaginal fistula. The patient was handed over to a distinguished general surgeon to be cured of this fistula. Efforts were made in a most careful manner to ascertain which ureter it was which had been wounded and become entangled in the vaginal cicatrix. These failing to afford definite information, the ureter of the suspected kidney was exposed through a lumbar incision and was temporarily ligatured. During this experiment, which was of course made under chloroform, no urine escaped by the vagina, but a certain amount was withdrawn by catheter from the bladder at the expiration of a given time. The inference was that the ureter temporarily ligatured was the one involved in the vaginal fistula; so the corresponding kidney was there and then excised. Imagine the surgeon's chagrin, and the patient's distress, the next day when it was discovered that, though she had lost a healthy kidney, the operation had not cured her of the fistula; for the wrong organ had been removed'.

Having ascertained which side is affected what should be done next? In three out of my 23 cases I have had the good fortune to force a catheter up an obstructed ureter with removal of the obstruction, followed by closing of the fistula. This experience leads me to recommend that serious efforts should always first be made to dilate the obstructed ureter through the cystoscope if exploration gives the least sense of the ureteral catheter or bougie being engaged in a stricture. The surgeon may notice after prolonged efforts, perhaps with a ureteral bougie or catheter which has been made more rigid by metal being interwoven in its structure, that the instrument is not easily withdrawn, giving the same sensation as that experienced when a gum-elastic bougie has become firmly engaged in a urethral stricture but has not passed through it. Further efforts may result in the passing of the catheter and cure may be expected.

If disappointment attend these attempts then the bladder should be opened.

The best results are to be obtained by resecting the lower end of the ureter through the bladder up to the site of the fistula and suturing the ureter into the bladder at a point above the fistula. The great advantage of an approach through the bladder is that, when the implantation is made, ample room can be left for the grafted ureter and all danger of the development of a narrow orifice avoided. On opening the bladder the previous observations are confirmed by passing a catheter up the intact ureter. A catheter is then passed on the fistulous side up to the site of obstruction. An incision is then made round the lower edge of the ureteral orifice and continued up the bladder wall. The lower end of the ureter is identified and dissected up until the fistula is reached. The lower part of the

ureter, including the fistula, is then cut off and the divided end of the ureter is loosely sutured into the base of the bladder. A small drainage-tube is passed through the bladder wall below the implanted ureter into the retro-vesical tissues and fixed in position by a catgut suture, and a catheter is left in the ureter. The rest of the wound in the base of the bladder is closed and the bladder is drained through the suprapubic wound. The small tube draining the retro-vesical space is brought through the suprapubic wound and the ureteral catheter through the urethra. The ureteral catheter is removed in two days' time. The small tube is removed as soon as it becomes loose, and the bladder tube at the same time.

Convalescence is usually uneventful and the result a perfect and permanent cure. The operation is one of some delicacy and difficulty and takes some time to perform. It is more tiring and exhausting for the surgeon than for the patient, for in spite of the time it takes to complete the operation it is not associated with any shock.

This is what I consider the ideal way of dealing with these cases and in my opinion it should always be attempted. Sometimes it cannot be accomplished. This is more likely in the cases resulting from Wertheim's operation. After Wertheim's operation an incision through the base of the bladder leads into dense fibrous scar tissue in which it is always difficult and sometimes impossible to identify the ureter. If the surgeon fails to dissect out the ureter he should not hesitate to open the peritoneal cavity. He can then trace the ureter down to the floor of the pelvis and draw the lower end into the bladder through an incision in its posterior wall placed as low down as possible. It is helpful to attach a thread to the lower end of the ureter to assist in pulling it through into the bladder. The peritoneum over the pelvic floor should then be carefully sutured and the peritoneal cavity closed. The surgeon can then proceed to deal with the implantation of the ureter from inside the bladder as already described.

In some cases when the ureter is isolated it is found to be dilated. This need not deter the surgeon from proceeding with the implantation provided the patient has not shown symptoms of severe kidney infection. Unfortunately the patient may not reach the surgeon until signs and symptoms of renal infection are well marked—pyuria, pyrexia, and pyelonephritis, and perhaps pyonephrosis. In such cases nephrectomy is indicated unless symptoms subside rapidly under treatment with urinary antiseptics.

In four of my cases the kidney has had to be removed because pyonephrosis had developed. It has been indeed a Delian sacrifice and has led me to urge that these cases should be dealt with early, when there is much more likelihood that success will follow attempts at catheterizing the ureter; operation, if necessary, will be easier than at a later date and the kidney will probably be saved. I have been able to pass a ureteral catheter on one patient comparatively easily when the fistula had only been present for a week and my colleague, Mr. E. W. Riches, has had a similar experience. Cure followed in both cases, though perhaps cure should not be attributed solely to this intervention as the leakage is sometimes only temporary. I have already mentioned cases in which I was successful in this manner and in one of these it was several weeks after Wertheim's operation. I still think, however, that the sooner the attempt is made after the development of the fistula the more likely it is to be successful. If the attempts to pass a ureteral catheter fail, operation for implantation of the ureter should not be proceeded with at once as the leakage may cease spontaneously, but operation should not be delayed more than a few weeks.

Conclusions

My experience leads me to the following conclusions:
1. All uretero-vaginal fistulae should be dealt with as soon as possible after being diagnosed. 2. In the

first place prolonged and even repeated attempts should be made to catheterize the ureters. 3. On the injured side obstruction is always found to the passage of the ureteral catheter when the fistula has been present for any length of time. 4. If catheterization fails the implantation of the proximal end of the ureter into the base of the bladder by an intravesical operation gives the best prospect of cure. 5. This implantation can be successfully carried out if the case is seen early, but after Wertheim's operation it becomes increasingly difficult as time passes and dense scar tissue develops. 6. In the event of failure to complete the graft by an intravesical operation the peritoneal cavity should be opened, the ureter isolated, and the grafting operation begun from outside and completed from inside the bladder. 7. In seriously infected cases the best procedure is nephrectomy through a lumbar incision.

The cure of this unfortunate disability may require all the skill, patience, tact, and determination to succeed with which the surgeon may be endowed. When success attends his efforts he will receive deep gratitude from the patient who has been relieved of a condition which was making life almost unbearable. If the surgeon has succeeded in curing the patient without the loss of a kidney he will in addition have the satisfaction of knowing that he has left her not only relieved of her distress but still endowed with her full renal efficiency.

Treatment of Puerperal Fever by Antistreptococcal Serum

By LEONARD COLEBROOK, M.B. (Lond.)

(From the *Lancet*, 11th May, 1935, Vol. I, p. 1035)

FOR 40 years antistreptococcal sera have been undergoing clinical trial all over the world for the treatment of puerperal fever. They are still very extensively used, but no agreement has been reached by clinicians as to their value. Most observers have seen the occasional patient whose temperature dropped in dramatic fashion following the administration of antistreptococcal serum (possibly a 'protein shock' effect, since this has sometimes happened with an infection which was not due to streptococcus); much more often they have seen the fever remit for a few hours only and the disease continue as before. It is not difficult to understand these discordant results and the many undoubted failures of serum therapy. The term 'puerperal fever' covers a very wide range of pathological conditions—from localized infections of the genital tract, parametric cellulitis, and thrombophlebitis, to generalized peritonitis, 'septicæmia' with or without metastatic foci, and endocarditis.

Critical judgment of the effect of any treatment will of necessity be very difficult in many of these conditions, for some of them—e.g., the infections which remain localized to the genital tract—carry a very high spontaneous recovery rate (nearly 100 per cent); while in others—e.g., fully generalized peritonitis and endocarditis—it is hardly to be expected that any therapeutic agent could overtake the infection. Moreover, these varied pathological conditions are now known to be produced by very different microbes. The hæmolytic streptococcus is responsible for about half of them; anaerobic and other types of non-hæmolytic streptococci, *B. coli*, staphylococcus, and other organisms are responsible for the rest. There is no doubt that during all these 40 years antistreptococcal sera have very often been employed in circumstances which did not allow of a specific curative effect.

The sera themselves have varied considerably. For about 30 years following Marmorek's work (1895) most workers aimed at producing a serum which was primarily antibacterial—i.e., one which would control the invasion of the tissues by the cocci. The possibility—and desirability—of producing an antitoxic serum was, however, not lost sight of (Marmorek,

Aronson, 1902), but the earlier attempts in this direction were not very successful. Since the war recognition of the fact that an exotoxin of the hæmolytic streptococcus ('Dick toxin') is produced in the human body—during scarlet fever, at any rate—and that this exotoxin can be neutralized, both *in vitro* and *in vivo*, by a highly antitoxic serum, has stimulated the hope that better therapeutic and prophylactic results might be achieved by such a serum than had been obtained with the antibacterial sera. The selection of good toxin-producing strains of streptococci for the immunization of the horses, and the improvement of technical methods for the concentration of the antitoxic fraction of the serum, have given us sera of much greater potency than those of earlier days, and these sera have been extensively employed in the treatment of puerperal fever for the past ten years. Many reports of individual cases, or of very small series, have been published, but these are of very little evidential value. On a broad view it may be said that those who have had most experience have been least convinced as to the efficacy of these sera. An analysis of a large series of cases, treated and untreated, by Benson and Rankin will be referred to later.

On the hypothesis that the toxins of puerperal fever strains might differ somewhat from those of scarlet fever, some laboratories have prepared sera from toxigenic puerperal fever strains.

Warnekros, Louros, and Becker reported 200 cases of puerperal fever treated with such a serum without a death. The cases are described as severe (*schwere*) but the clinical data given are extremely scanty. We are not told whether there were any cases of peritonitis nor how many of septicæmia (hæmolytic streptococci in blood culture); nor indeed how many cases were infected by that microbe. Nor is there any estimate of the recovery rate in a comparable series of unselected cases not treated by serum. From the fact that 4 of the 6 patients whose temperature charts are reproduced (presumably among the most severe) are stated to have had no microbes in the blood, while the 2 remaining cases grew respectively three and five colonies from the blood, it seems probable that a large proportion of the cases presented merely a localized infection which normally carries a recovery rate of approximately 100 per cent.

In 1928 Gaessler reported a further 400 cases from the same clinic with 20 deaths; 299 of his cases were admitted with little or no fever on account of difficult labours but subsequently became more or less febrile. In this series, as in the former, there was no distinction between cases infected by hæmolytic streptococci and those which were not, and the very meagre clinical data do not permit of any judgment as to the effects of the serum. Later reports do not seem to support these first claims to success.

Still more unsatisfactory as a statistical study is the analysis by Lash (1929) of 57 cases treated with a similar serum made from puerperal fever strains. The death rate among these cases was 32 per cent, but this compared favourably with that of a control group (treated in other ways) of 13 selected cases which showed a death rate of 61 per cent. Fortunately details are given of these control cases, and it is seen that they comprise 8 cases of septicæmia and 7 of 'peritonitis or beginning peritonitis'—scarcely a representative sample of ordinary puerperal infections.

In 1929 H. Vincent introduced a 'new' serum which has been extensively used in France. The method of its manufacture has not been disclosed, but there seems no reason to suppose that it rests on any new principle. No evidence has been given that it can either prevent or cure an infection by hæmolytic streptococci in animals, but in a recent paper Vincent (1934) has claimed that by the use of enormous doses (1,300 c.cm. in one child) no less than 180 (82.5 per cent) of a series of 218 cases classed as 'septicæmia and meningitis' have been cured. This remarkable claim demands careful examination. Such examination shows that there has not been personal observation of

the cases. They have been collected from the numerous published reports of the medical press of France and other countries and of reports of cases sent to him privately. The published reports deal almost invariably with one or occasionally two cases of recovery, and they attribute that recovery unequivocally to the serum even when many large doses were required before the temperature fell. Frequently other forms of treatment were employed at the same time. These individual case reports tell us nothing at all about other cases treated who have not recovered.

In assessing the value of such evidence I think one should not forget that many medical men will publish individual successes while few will broadcast failures. It might well be that if *all* the cases of 'septicæmia and meningitis' treated by this serum were faithfully recorded the result would be very different. Again, there is some doubt as to the sense in which Vincent uses the words 'septicæmia and meningitis'. He does not tell us categorically in how many cases hæmolytic streptococci were grown from the blood, nor in how many from the cerebro-spinal fluid, but he does mention in a footnote that some cases were included although their blood culture was negative. His claim that the recovery of the 180 cases was due to serum and not to 'natural causes' appears to rest, however, on the summary statement that '*Le septicémie à streptocoques comporte un pronostic fatal*' (1929).

That statement does not agree with my personal experience of hæmolytic streptococcal septicæmia (with positive blood culture). With Dr. R. Hare I have reported (1934) 19 such cases (excluding cases of generalized peritonitis) observed during the years 1928-33 which showed a recovery rate of 41 per cent; and in a further series of 15 such cases observed during 1934 at Queen Charlotte's Hospital no less than 11 have recovered (73.3 per cent). Seven of these 15 cases gave a positive blood culture on more than one occasion, and five of the seven recovered. In none of these cases was specific treatment used. The recovery rate of 73 per cent is probably quite unusual, but it serves to show how cautious one should be in attributing recovery in septicæmia to any particular remedy.

My impression after a careful study of these clinical reports—and of many which preceded them—is that none of them justify the conviction that antistreptococcal sera have really shown an indubitable effect upon the puerperal infections by hæmolytic streptococci. (I am purposely excluding scarlet fever from this survey, partly because I have no experience of it, and also because the rationale of treatment by an antitoxic serum in that disease is on quite a different footing.) If such a curative effect is to be clearly demonstrated in the human subject, it must be by application of the treatment to large groups of cases known to be infected by hæmolytic streptococci, and by critical comparison of their records with those of cases similarly infected but untreated. Both groups must be under the direct observation of the same individuals and the bacteriological data should be obtained in the same laboratory.

Investigations of this kind carried out for the first time during the last few years will now be described.

Benson and Rankin (1933) have reported upon 114 puerperal cases observed in Edinburgh. Half of them had received serum and half had not. The two groups comprise all the cases from whom a positive blood culture (hæmolytic streptococcus) was obtained during a period of several years. (It is important to note, however, that many of the serum-treated cases were only found to be 'blood positive' at some period *after* the commencement of serum treatment.—Personal communication from Dr. Benson.) In 28 per cent of them the treatment was commenced within 48 hours of the onset of fever. Of the 57 serum-treated cases 37 received scarlet fever antitoxin and 20 'puerperal antistreptococcus serum' (which also contained some antitoxin). The authors state that both sera were manufactured by Messrs. Burroughs Wellcome and Co.

In 74 per cent of the cases the serum was given intravenously as the makers recommend. The mortality rate in the 57 serum-treated cases was 75 per cent as compared with 68 per cent in the control group. In view of the 'several days of misery in the form of serum sickness', the great expense (nearly £300 for the 57 patients) and the absence of any evidence that the treatment had any beneficial effect, the authors recommend that the giving of serum '*faute de mieux*' ought to be discontinued.

EXPERIENCE OF SERUM-TREATED CASES AT QUEEN CHARLOTTE'S HOSPITAL

Comparison of 69 cases treated with antistreptococcal or antiscarlatinal (antitoxic) serum before admission to Queen Charlotte's Hospital with other cases not so treated (1930-34).

CASES TREATED BY SERUM

Infected by hæmolytic streptococci 40 (58 per cent)
Not infected by hæmolytic streptococci 29 (42 " ")

ALL CASES OF PUERPERAL PYREXIA ADMITTED TO HOSPITAL

Infected by hæmolytic streptococci 60.8 per cent
Not infected by hæmolytic streptococci 39.2 " "

DEATH RATE OF THE SERUM-TREATED CASES AND OF THE CASES WHO HAD NO SERUM

	Cases	Deaths	Case mortality (per cent)
All cases treated with serum before admission ..	69	21	30.4
All cases who had no serum	932	108	11.6
Hæmolytic streptococcus cases—			
Treated with serum ..	40	18	45.0
Treated without serum	346	70	22.3

Antistreptococcal sera have not been used at the Isolation Block of Queen Charlotte's, but 69 cases during the last four years had been given serum before admission. Most of them were sent in by private doctors and they came from all parts of the Greater London area.

Certain data obtained from the records of these 69 cases—and of the cases who received no serum—are shown in the table.

COMMENTS ON THE TABLE

(1) It is unfortunately not possible to give complete and entirely reliable data as to the exact kind of serum used in every case, its amount, or the route by which it was administered, because there was often difficulty in getting all these details from the doctor who sent in the case. So far as the records serve they show that the serum was always derived from laboratories of good repute, that 39 cases got 'antistreptococcal serum' and 30 scarlatinal (antitoxic, concentrated) serum. One case had both. Thirteen cases had more than one dose. The amount of serum varied from 10 c.cm. to 140 c.cm. In most of the cases it was given intramuscularly.

(2) Since the 69 cases were treated by serum before admission to the hospital it is not possible to describe their condition at the time when the treatment was begun. In about 75 per cent of the cases the first injection was given within 48 hours after the onset of fever—often within 24 hours. After admission to the hospital all cases were treated on precisely the same lines. Glycerine was usually instilled into the uterus several times daily for the first few days and the

patient's strength maintained by good feeding and nursing. In the great majority no specific treatment of any kind was used.

(3) It will be seen that over 40 per cent of the cases treated by serum were not infected by hæmolytic streptococci and were therefore subjected to the risk of serum sickness without any prospect of a specific immunizing effect.

(4) The mortality rates for the 69 cases treated by serum and for all cases who had no serum show a very big difference, but it would be a mistake to attach much importance to this, because these two groups are obviously unsatisfactory statistical material. Both include many cases not infected by hæmolytic streptococci and also a certain proportion of cases in which the fever was really of extragenital origin—*e.g.*, cases of urinary infection, mastitis, bronchitis, and so forth. It is of interest to note in passing, however, that an examination of the published records of similar unselected cases of puerperal infection by a committee of the American Gynecological Society in the early days of serum treatment (1899) gave very similar figures: 352 serum-treated cases showed a mortality three to four times as high as 138 cases which had no serum. The committee rightly recognized that the data were not entirely reliable and did not therefore permit of a very emphatic statement of conclusions. Nevertheless it ventured the opinion that more patients were dying from the treatment than from the disease.

(5) The figures that merit most consideration are, of course, those showing the mortality rates in the two groups infected by hæmolytic streptococci. Clearly it is difficult to deduce from them that the treatment by serum had any beneficial influence upon the infections—and this in spite of the fact that in 75 per cent of the cases serum was given within 48 hours of the onset of fever—often indeed within 24 hours.

The important question remains. Did the serum actually, as the figures suggest, contribute to the unusually high death rate among the 40 cases? This is such a serious issue that the data demand the most critical scrutiny.

I have considered the following possible sources of fallacy:—

(a) *That serum was given only to the cases who seemed most gravely ill.*—This consideration may well have been operative in a small number of the cases but not, I think, in a large proportion of them. My reason for that opinion is as follows: it is well recognized by all who have much experience of puerperal fever that the cases most gravely ill during the first week are those infected by hæmolytic streptococci. If serum had been reserved for these most severe cases one would expect to find a very high percentage (not less than 80 per cent) of infections by hæmolytic streptococci among the 69 cases so treated. But only 58 per cent were so infected—a figure actually a little lower than that for all cases admitted to the hospital. No less than 29 of the 69 cases, although they were given serum, had not an infection by hæmolytic streptococcus, and, as is usual in such cases, these 29 cases carried a low mortality rate (10 per cent). Moreover, a survey of the records of the 40 hæmolytic streptococcus cases treated by serum shows quite clearly that many of them were never gravely ill.

In my opinion therefore we must conclude that the whole 69 serum-treated cases represent just an average sample of febrile disturbances in the puerperium; and that most of them were given serum because they happened to be in the care of a medical man who believed that as soon as a woman developed fever in the puerperium it was best to employ that remedy. Even, however, if we suppose that 5 of the 40 hæmolytic streptococcus cases were given serum because the clinical condition was judged to be unusually serious, and that all the 5 died, there still remains a mortality rate of 37 per cent for the other cases whose selection was probably not determined by this special consideration.

(b) *That the 40 serum-treated cases were admitted on the average somewhat later than those who had no*

serum—and for that reason did not gain such benefit as may accrue from the routine treatment and specialist care in this hospital.—It has been our experience that early admission—particularly of the cases infected by hæmolytic streptococci—is definitely correlated with a high recovery rate. On working out the time of admission of the serum-treated and other cases, however, it does not appear that this consideration can have influenced the mortality rates shown in the table. The 69 serum-treated cases were admitted on the average 7.8 days after labour; the 40 hæmolytic streptococcus cases 8.0 days; the 18 fatal hæmolytic streptococcus cases 7.8 days; and 76 control cases, consisting of 19 consecutive cases chosen at random from each of the four years, 7.8 days.

(c) *That many of the infections among the 40 serum-treated cases had occurred in epidemics or during periods when the prevalent infections were of an unusually severe type.*—Actually only 4 of the 40 serum-treated cases originated in small epidemics (and 2 of them recovered). Both serum-treated and control groups were made up chiefly of sporadic cases spread over the four years. The mortality rate among the 346 cases infected by hæmolytic streptococci never rose above 28 per cent for any one year.

My opinion, after all consideration of these possible fallacies, is that the greatly increased mortality rate in the serum-treated cases was due either to the serum having exerted an unfavourable effect—turning the scale against their recovery—or to the operations of chance. Choice between these alternatives is not easy. On the one hand, it is obvious that very many and very large doses of serum have been repeatedly given to human beings without apparent harm. On the other hand, evidence is not lacking which indicates that the injection of a foreign serum may sometimes be definitely prejudicial to infected human beings and animals. A. Jousset (1924) and P. Courmont (1934) have emphasized these adverse effects in connection with experimental tuberculosis (guinea-pigs) and with phthisis in man.

The most striking evidence relating to streptococcal infections is that of Penfold and Butler (1932), who observed that both normal horse serum and anti-streptococcal sera, given to mice at the same time as a dose of living streptococci, would sometimes hasten the death of the animals. The conditions in the infected human subject under treatment by serum are admittedly quite different from those of the mouse experiments and it does not therefore follow that the therapeutic sera will necessarily exert a similar effect in the two cases, but, until we have more understanding of the mechanisms involved, that possibility cannot be ignored. Pointing in the same direction is the recent warning by B. Schlesinger (1935) against the danger of giving antistreptococcal sera to children with acute rheumatism which in his experience is not infrequently 'reactivated' by such treatment.

All this evidence, taken together with the well-known, but little understood, 'toxic' effects of horse serum, ought, I think, to be taken into account before we subscribe to the dictum so often expressed that 'a dose of serum can at any rate do no harm'. Can we be sure that an agent capable of causing such profound disturbances as those associated with anaphylaxis, serum sickness, and agglutination of red corpuscles (the extreme degree of incompatibility between horse serum and human reds does not seem to have been generally recognized), will not sometimes have an adverse effect upon the complex mechanisms concerned in immunity to infective diseases? I would suggest that our view of serum therapy has in the past been somewhat unbalanced. We have focused attention too exclusively upon its antitoxic or antibacterial qualities and rather lost sight of the 'toxic' potentialities which have to be set off against them. The possible benefits of passive immunization probably must always be paid for. Sometimes, as in the case of diphtheria antitoxin, the price may be well worth while—in other cases, as

perhaps in the case of antistreptococcal serum, it may be too heavy.

At Queen Charlotte's, if we had given serum to all cases infected by hæmolytic streptococci, and if they had had the same death rate as in the 40 cases so treated before admission (*vide* table), there would have been approximately 86 more deaths than actually occurred during the years 1930-34.

It would not be profitable to set out in full the results of a critical survey of all the experimental work published in connection with antistreptococcal serum, because so many points are left in doubt and require reinvestigation in the light of new knowledge about the group of hæmolytic streptococci. The following brief summary and references may, however, be useful:—

PROTECTION EXPERIMENTS

(1) By the immunization of horses, rabbits, and sheep, sera have been obtained which, when given some hours in advance of the infecting dose, would protect mice and rabbits against 1,000-100,000 M.L.D. of the strain used for immunization (Marmorek, Bordet, Aronson, Neufeld, Simon, Dochez, Avery, Lancefield, Yoshioka, Lancefield and Todd).

(2) It appears that these highly effective sera have only been produced with streptococcal strains of exceptional virulence, resulting from frequent passage through animals.

(3) Some of these protective sera were more active against other strains of hæmolytic streptococci than that used for the immunization of the horses [Sommerfeld, Neufeld (1903), Simon]; and it is possible (although not proven) that these other strains were sometimes of different serological type. On the other hand, the work of Dochez, Avery and Lancefield strongly suggests that the protection afforded by such sera is strictly type specific.

(4) It is not clear that the protective sera thus obtained by immunization with highly virulent 'passage strains' have ever been effective strains of moderate or low virulence such as are habitually isolated from human infections—e.g., puerperal fever, surgical sepsis, etc.

(5) The mechanism of protection by the highly active sera has not been adequately established, but the work of Bordet, and particularly that of Neufeld and Rimpau, seems to show that their capacity to render the very virulent streptococci susceptible to phagocytosis ('bacteriotropin effect') is a very important factor.

(6) Sera produced by the injection of toxigenic cultures of hæmolytic streptococci, or by filtrates of such cultures, into animals, are capable of neutralizing that toxin both *in vitro* and *in vivo* (Parish and Okell, Hartley, Pulvertaft). When a potent antitoxic serum is injected into rabbits in advance of a large dose of an avirulent culture containing such toxin, the life of the animals is prolonged, or sometimes saved (by virtue of the neutralization of the toxin), but infection of the tissues is not prevented (Parish and Okell). [It may be mentioned also that the active immunization of human beings by Dick toxin does not render them immune to infections by hæmolytic streptococci—as judged by the incidence of tonsillitis among the immunized staffs of fever hospitals (Benson and Rankin, 1934)].

(7) The commercial sera issued in recent years have at best only a very slight protective action against hæmolytic streptococci freshly isolated from acute septic infections of man even when they are given some hours in advance of the infection. When given at the same time as the infecting dose of streptococci they occasionally prolong the life of the test animals by a few days, more often they show no effect at all, and sometimes they definitely hasten death (Penfold and Butler).

CURATIVE EXPERIMENTS

Besredka (1904) and Aronson (1905) record that a highly protective serum obtained by the immunization

of horses with a very virulent 'passage strain' was able to overtake a rapidly fatal septicemic infection of mice if it was given within 12-24 hours after the infecting dose of homologous culture. Repetition of the serum dose was sometimes necessary. Besredka's statement is the more precise. He says that 1/40-1/100 c.c.m. of serum would suffice to save mice infected 18-24 hours previously with 2,000 M.L.D. of culture.

I have failed to find evidence that the commercial sera now available have the *slightest* curative effect in infected animals.

In vitro EXPERIMENTS

The antistreptococcal and antitoxic sera at present available have not been shown to possess any bactericidal power. Hæmolytic streptococci will grow in them. Nor have these sera any power to promote the phagocytosis of virulent streptococci (bacteriotropin effect) (R. Hare).

I believe it is correct to say that most of the laboratories producing these sera do not test them at all for any antibacterial (as opposed to antitoxic) properties.

Conclusions

1. There is no trustworthy clinical evidence that the administration of antistreptococcal serum for the treatment of human infections by hæmolytic streptococci has had any specific curative effect. (A possible effect on the toxic manifestations of scarlet fever is purposely excluded from this statement.)

2. The evidence obtained in puerperal fever cases at Queen Charlotte's Hospital suggests that such administration may sometimes have an *unfavourable effect* upon puerperal infections by hæmolytic streptococci; and this impression is to some extent supported by the evidence of animal experiments. All our experience carries the lesson that it is in the best interest of the patient suffering from an infection by hæmolytic streptococci not to interfere with her immunizing mechanisms (about which we know so little as yet) until we can be sure that such interference does not do harm.

3. Although sera have been produced which would protect animals against infection by streptococci of artificially enhanced virulence, there is no satisfactory evidence that a serum has ever been produced which would afford more than very slight protection (occasionally) against hæmolytic streptococci freshly isolated from acute human infections and of various serological types.

4. Similarly there is no evidence that any antistreptococcal serum has ever exerted a *curative effect* in animals infected by such hæmolytic streptococci freshly isolated from human infections.

5. It is a matter for regret that antistreptococcal sera should have been issued for clinical trial so long before satisfactory experimental evidence as to their curative effects in animals was available—or a strong presumption existed (from unequivocal *in vitro* experiments) that such a curative effect would be obtained in man. Until our knowledge of immunization against the hæmolytic streptococci has progressed further it would seem desirable to discontinue the use of antistreptococcal sera in the treatment (and prophylaxis) of puerperal fever and 'surgical sepsis'.

Theories on the Genesis of Gastroduodenal Ulcer

(From the *Journal of the American Medical Association*, Vol. CIV, 4th May, 1935, p. 1637)

THE circulatory theory of the genesis of gastric ulcer advanced by Virchow and Hauser in 1853 suggested that such ulcers are produced by an infarction of a terminal blood vessel with consequent necrosis, the starting point for the digestive action of the gastric juice. In this theory the rôle of the excessive gastric secretion assumed especial importance and was considered the decisive factor by Riegel, Boas, Sippy, von Bergmann and, in fact, the majority of clinicians

Chronic ulcers, it was pointed out, occur only in that portion of the gastro-intestinal tract which is exposed to the action of the hydrochloric acid; *viz*, the stomach and the first two inches of the duodenum. They are rare in the cardia. When the jejunum is exposed to the action of gastric juice following a gastro-enterostomy for ulcer, marginal peptic ulcer develops not infrequently. However, such ulcer has never been observed when the gastro-enterostomy is performed for gastric cancer. Of particular interest are the peptic ulcers of Meckel's diverticulum, in which histologic studies revealed the presence of islands of gastric mucosa in the diverticulum. The ulcer itself is analogous to the marginal peptic ulcer. Ulceration here is ascribed to the peptic effect of the gastric juice on the adjacent intestinal mucosa.

The wave of enthusiasm for stomach resections, which began about twenty years ago and was advanced with particular fervour in Germany, supplied abundant material for histologic studies and a new point of view. In all cases of gastric or duodenal ulcer, gastritis or duodenitis appeared. The inflammatory areas frequently contained multiple small, oval, round and linear erosions, the largest of which could be recognized macroscopically as superficial erosions. The fact that he failed to find any change in the blood vessels in these areas was stressed by Konjetzny, who did not observe any evidence of hæmorrhage, anæmic necrosis or hæmorrhagic infarction. Inflammatory changes in the mucosa without any evidence of peptic digestion were, however, observed with great regularity. Konjetzny, Puhl, Moscovitz, Kalima and others, supported by histologic studies, established that ulcerative gastritis or duodenitis is the important factor in the pathogenesis of the ulcer disease. Inflammatory gastritis and duodenitis were the precursors as well as the accompanying anatomic factors and explained the chronic course of the disease with its remissions and exacerbations. These observers denied the importance of pepsin hydrochloric acid in the conversion of an erosion into an ulcer. The neurogenic-spasmogenic theory of von Bergmann was based on the clinical observation that many of the patients with ulcer exhibited disturbances of the vegetative nervous system. Eppinger and Hess suggested that vagotonia provoked spasms of the muscularis and of the muscularis mucosæ, leading to areas of ischæmia, which favoured the formation of erosions and ulcers. A spastic condition of neurogenic origin operating on the vessels and

the muscular apparatus was the causative factor. But experiments on severing the vagi and on extirpating the sympathetic and the celiac plexus gave contradictory results, and the hypothesis that all bearers of ulcer are vagotonic or sympathicotonic did not find acceptance.

The mechanical-functional theory advanced by the Aschoff school was based on the existence of a special anatomic unit. The gastric channel of Waldeyer, 'the magenstrasse', occupying the lesser curvature, is the seat of 90 per cent of all gastric ulcers. The contention that food and gastric juices move along this path to reach the pylorus, thus exposing it to greater mechanical and chemical injury than the rest of the gastric mucosa, is not supported by the more recent roentgenologic studies. The accumulated clinical and experimental observations force the clinician and the experimental worker once more to look to the digestive power of the gastric secretion as the most important factor in the genesis of the ulcer. The next step was an attempt to produce ulcers in normal gastric mucosa by increasing the amount of the secretion as well as its digestive power. Birkle-de la Camp was able to produce ulcers in rats by subjecting them to starvation and to hypodermic injections of histamine in doses sufficient to stimulate the secretion of the gastric juice but not sufficient to cause spasmodic contractions of the gastric vessels or the musculature. The ulcers thus produced exhibited a tendency to invasion, bleeding and perforation. These effects could be produced only in fasting stomachs; but fasting alone without injections of histamine failed to produce ulceration of the gastric mucosa. Sectioning of both vagi did not cause ulcer formation unless combined with histamine injections. The rôle of the gastric secretion in the genesis of ulcer was demonstrated even more strikingly in Silbermann's experiments. Silbermann established œsophageal fistulas in dogs and subjected them to sham feedings, thus stimulating the psychic phase of the gastric secretion. The stomach continued to secrete after each feeding a secretion of acid concentration and digestive power five times as great as that of the normal secretion. When examined from fourteen to forty-nine days later, all the dogs showed ulcerations in varying stages of development. Silbermann's experiments demonstrated that excessive gastric secretion of high digestive power is capable of producing severe gastric lesions and fibrinoid necrosis and that the experimental ulcers are localized almost exclusively in the pyloric region.

Reviews

THE AUTONOMIC NERVOUS SYSTEM.—By A. Kuntz, Ph.D., M.D. Second Edition. 1934. Baillière, Tindall and Cox, London. Pp. 697. Illustrated with 73 engravings. Price, 35s.

As far as medical science is concerned it is a fairly general rule that the less known about a subject the more voluminous the literature. This volume is certainly large and although a really satisfactory theory of the exact nature and significance of the autonomic nervous system has yet to be advanced, the author has made an exceedingly good survey of the field. He has covered the anatomical, experimental, clinical and theoretical sides and despite our ignorance has brought forth a considerable amount of both useful and interesting information. The anatomy, histology and embryology is described in detail in the beginning followed by a chapter on the pharmacology of the autonomic nervous system. Probably in no branch of physiology has pharmacology proved such a useful handmaid in the elucidation of function as in this field. The autonomic innervation and in certain cases cortical representation of every part of the organism is taken up along with a discussion based on experimental and

clinical data of its function in each particular instance. The theory of autonomic balance and imbalance is then discussed. There can be no doubt about the fact that the true sympathetic system (the chain of ganglia and nerve offshoots connected to the cord from the second thoracic to the fifth lumbar vertebra) on the one hand and the parasympathetic system (cranial autonomic oculomotor VIIIth nerve—vagus and sacral branch—pelvic nerve) on the other are in general antagonistic in action on any particular system.

This fact led Eppinger and Hess in 1909 to put forward the conception of sympathicotonia and vagotonia based largely on clinical work.

Vagotonics showed in general a preponderance of vagal effects such as a slow heart, tendency to diarrhœa, dry skin, etc., while sympathicotonics were highly strung, tended to perspire easily and were subject to tachycardia. The theory is not complete however as most subjects showed features of both types of activity. Later workers however suggested that it is not a case of preponderance of one system but an enhanced activity or irritability or both. In Graves' disease for instance one sees tachycardia and perspiration along with diarrhœa significant of vagal overactivity.

Much remains to be done in this field but undoubtedly Eppinger and Hess expressed a fundamental truth. A number of clinical observations and surgical applications are given and the book should be a stimulant to an enthusiastic and observant clinician in any branch of medicine. Probably in no branch of physiology is more information to be obtained on this system than by careful observation of the human subject in health and disease. There can be no doubt that the influence of the mind on the body and *vice versa* must be effected through this system—a fact which possibly explains the conflicting or negative results often obtained by animal experiments in this field where the higher cerebral function is less in evidence. One omission might be mentioned, namely a discussion of the mechanism of humoral excitation, and the newer knowledge of adrenergic and cholinergic fibres. The recent knowledge of the effect of choline and adrenalin or adrenalin-like substances has done much to clear up some anomalies in the system based on anatomical and pharmacological evidence—namely the sweat glands which are anatomically pure sympathetic and yet respond to pilocarpine, a vagotonic drug. The book is well written and contains a full list of references.

H. E. C. W.

DIETETICS FOR THE CLINICIAN.—By M. A. Bridges, B.S., M.D., F.A.C.P. Second Edition. 1935. Henry Kimpton, London. Pp. xxiii plus 970. Price, 45s.

THE attainment of scientific and correct principles as regards the treatment of a disease is not confined to the drug therapy alone but a good deal of it lies in a proper and systematic adjustment of the diet. It is therefore gratifying to note that continued and increasing interest is being shown by present-day clinicians towards this important and hitherto neglected subject, which unfortunately in the past was left to the control of the housewife alone.

The marked improvement which is brought about by the dietetic management of a typhoid patient has been an eye-opener to many and even the die-hard old clinicians were not slow in recognizing its value. The change from the low (1,000 calories or less) to high caloric diet has now been welcomed by most clinicians as a valuable aid in the management of these cases.

The same remark applies to cases of tuberculosis, where, in addition to the high caloric diet, a diet rich in calcium and vitamin content is nowadays advocated, with gratifying results.

Then again, the value of ketogenic diet in certain types of epilepsy is steadily gaining ground.

The value of ketonuria as produced by diet on certain types of bacilluria is now almost established. It has been proved by experiment that urine with a pH value of 5.5 to 5.2 or less in conjunction with beta-hydroxy-butyric acid content of 0.5 per cent has a bactericidal action on certain types of colon bacilli.

This book contains a mine of useful information on the subject of diet therapy in different diseases and Dr. Bridges deserves the congratulation of the profession in bringing out the present edition based on sound and practical reasoning to account for the dietary advice he has given for different diseases and we feel no doubt that his book will be widely welcomed by the medical profession.

J. P. B.

THE KIDNEY IN HEALTH AND DISEASE.—Edited by H. Berglund, M.D., and G. Medes, Ph.D. 1935. Henry Kimpton, London. Pp. xix plus 754. Illustrated with 163 engravings. Price, 45s.

THIS book is the outgrowth of a symposium participated in by forty-one contributors, mostly American, though the senior author, Professor Berglund, is a Swede, formerly a professor of medicine in Minnesota.

The book abounds in references to the work of American, German and French investigators, but to relatively few British writers. This will probably tend

to diminish the interest of the British reader; though it must be admitted that it would be difficult to find a work as detailed and as comprehensive written by a British author on the kidney.

The first part of the book is concerned with the morphology of the kidney including comparative anatomy; the functions of the glomeruli and tubules in vertebrate and invertebrate animals is also dealt with. Particular attention is paid to the processes of filtration, reabsorption and glomerular blood flow.

Part II is concerned with the biochemistry of the kidney in health and disease; part III with the pathological and clinical aspects of the various forms of nephropathy, renal anomaly and renal infection, and also the relationship of the kidney to arterial hypertension.

Albuminuria and œdema are dealt with in part IV, ocular changes in part V, and the clinical aspects of Bright's disease in part VI.

The book is plentifully illustrated with excellent prints and diagrams. Relatively far greater attention is paid to morphology, biochemistry and pathology than to the clinical aspects, the symptomatology and the treatment of kidney diseases. Prognosis is almost entirely neglected.

The description of the pathology and bacteriology of kidney infections is detailed and extensive but the treatment of these conditions is very inadequately described. The symptomatology and treatment of hypertension is particularly sketchy though the description of the pathology of the condition is lucid and adequate; no mention has been made of the therapeutic use within recent years of muscle extracts, though the empiric use of magnesium sulphate in the hypertension of acute nephritis has been given a place. No treatment has been given for the most important condition of uræmia. In a book of this kind that is a serious deficiency—a description of the treatment of a condition like this is what the practitioner needs most of all. The scientific study of kidney function is very interesting, but a knowledge of the practical aspect of kidney disease is an infinitely more urgent need.

Notwithstanding these deficiencies the book is a very valuable one and one of the most extensive studies of this subject in the literature. The part of the book dealing with œdema is particularly good and the section on ophthalmoscopic appearances in kidney disease is very excellently described. The book is very readable and interesting.

T. H. T.

CHRONIC NASAL SINUSITIS AND ITS RELATION TO MENTAL DISORDER.—By F. A. Pickworth, B.Sc., M.B., B.S., A.I.C. (Exam.). 1935. H. K. Lewis and Company, London. Pp. xii plus 156 with 83 illustrations. Price, 16s.

THIS work is intended as a work of reference for those engaged in research work on mental diseases and so does not lend itself to an abstract.

To be appreciated it must be read in the original. The book is beautifully got up. All the illustrations are from original specimens. The reproductions are from untouched photographs. There are four sketches in colour by well-known medical artists and each is a work of art in itself.

The work originated when the author found sepsis in the sphenoidal sinus while he was investigating the histology of the pituitary gland of mental hospital patients. In this book he demonstrates the existence, extent and complications of chronic nasal sinusitis occurring in mental hospital patients. He also demonstrates the mechanisms by which such chronic disease results in those physical changes in the brain tissue which are present in cases showing symptoms of mental disorder.

In addition to his main thesis the author gives a practical clinical and pathological picture of mental disorder which is based upon functional changes of the cerebral capillaries.

He hopes that in future the clinician will try, at least, in his own mind, to correlate the symptoms of mental disorder with disturbed vascularity of the brain, and that the pathologist will associate his pathological, bacteriological and biochemical findings with their possible effect on the state of the brain capillaries.

The book will not only interest the specialist concerned but also the general practitioner as well.

Dr. Pickworth has made a contribution to the aetiology of mental disorder of the very highest importance. In support of this statement is the fact that nowadays all the large mental hospitals in Great Britain have an experienced rhinologist in their service.

H. S. C.

MODERN CLINICAL SYPHILOLOGY: DIAGNOSIS—TREATMENT—CASE STUDIES.—By John H. Stokes, M.D. Second Edition. 1935. W. B. Saunders Company, Philadelphia and London. Pp. 1400, with 973 illustrations. Price, 50s.

DR. STOKES and the other collaborators deserve to be highly congratulated for bringing out the second edition of their excellent and exhaustive book entitled *Modern Clinical Syphilology*. This edition consists of 24 chapters of 1400 pages and 973 illustrations, and deals with every aspect of syphilology in a clear and comprehensive manner. The medical student, the general practitioner, and the venereal specialist will all find the book equally interesting and instructive. Chapter I begins with a description of the spirochete and the pathological and immunological responses of the body to infection. Chapter II deals with the distribution of syphilis in the general population and the method of obtaining histories of cases. Chapter III, which is profusely illustrated, describes the method of examination of cases. Chapter IV describes the dark-field examination for spirochaetes in great detail and also the methods of staining spirochaetes. Chapter V deals with the serological tests on blood and spinal fluid and in it one finds many valuable practical hints on the Wassermann and flocculation tests. Chapters VI, VII and VIII are devoted to a general consideration of the principles in treatment and the uses of heavy metals and arsenicals. The subject is excellently dealt with. Chapter IX is devoted entirely to a description of various technical methods employed in treatment. Details regarding asepsis, preparation of drugs for intramuscular and intravenous injections, performance of lumbar and cisterna punctures and intraspinal medication are all given. Chapter X deals with the reactions and complications following treatment as well as contra-indications to treatment. This chapter will be found extremely helpful by the general practitioner. Chapter XI deals with some of the important problems connected with treatment of syphilis during latency and intercurrent disease and gives details regarding medicinal prophylaxis. Chapter XII deals with the clinical diagnosis of syphilitic chancre and chapter XIII with the manifestations of secondary syphilis and their diagnosis. Chapter XIV deals with relapse, reinfection and progress of early syphilis and chapter XV deals with the treatment of these conditions. Chapter XVI which is again profusely illustrated deals with late lesions of the skin and mucous membrane in syphilis and chapter XVII consists of a description of syphilitic lesions of the skeletal system. Chapter XVIII deals with syphilis of the gastro-intestinal tract and chapter XIX with syphilis of the liver and spleen. Chapter XX is devoted to cardio-vascular syphilis and chapter XXI to a consideration of syphilis of the nervous system. Chapter XXII deals with familial and congenital syphilis. Chapter XXIII deals with miscellaneous aspects such as syphilis of the lung and mediastinum, kidney, ureter, and bladder. The last chapter deals with the public health aspect of syphilis and includes a brief account of social service organization and sex problems. If one patiently goes through this voluminous book one is greatly impressed not only by the amount of information contained in it but also by the

soundness of the views expressed by the authors on controversial matters. It is an excellent reference book which should find a place in every important medical library. It is quite up to date and contains references to most of the recent work on the subject. The large number of illustrations and the synoptic tables in almost all the chapters are a special feature of the book and they greatly enhance its usefulness.

K. V. K.

A HANDBOOK OF MIDWIFERY—FOR OBSTETRIC DRESSERS, PUPIL MIDWIVES AND MIDWIVES.—By Sir C. Borkoley, M.A., M.C., M.D. (Cantab.), F.R.C.P. (Lond.), F.R.C.S. (Eng.), M.M.S.A. (Hon.), F.C.O.G. Ninth Edition. 1935. Cassell and Company, Limited, London. Pp. x plus 634, with colour frontispiece and 76 illustrations in the text. Price, 8s.

SINCE this excellent handbook has now reached a ninth edition it needs no further commendation. Its qualities of conciseness, clear arrangement and good illustrations have made it a favourite book with midwives in England for three decades. The Indian midwife would appreciate it equally with her English colleague if there were a vernacular edition which she could use when preparing for her examination or when in search of a rapid reference. Notes on tropical anaemia of pregnancy, osteomalacia and the various tropical diseases associated with and influencing the course of pregnancy would be necessary in an Indian edition.

One hundred pages in a book of some 600 pages are devoted to the child. The teaching is dogmatic, feeding alternatives are rarely suggested and no distinction is apparently made between complementary and supplementary feeding. As the midwife may later become a health visitor it is unfortunate that her subsequent teaching may not always be in conformity with what she has been taught as a midwife. The need to limit the size of a handbook accounts for omissions and in the introduction the midwife is referred to the *Mothercraft Manual* to supplement her knowledge of the child.

J. M. O.

MEDICINE: DISEASES OF THE NERVOUS SYSTEM. Third Edition. Part V. (Catechism Series.) E. and S. Livingstone, Edinburgh. Pp. from 381 to 476. Price, 1s. 6d. Postage, 2d.

THE 'Catechism Series' is too well known to need an introduction. In a series of this kind it must be presumed that the student knows his anatomy and physiology of the nervous system, that he has read his textbooks and attended the lectures on nervous diseases. He would then find it useful for quick revision of the subject.

Although this is a revised and enlarged edition, one could not find the mention of 'convalescent serum' in the treatment of acute anterior poliomyelitis, 'lumbar puncture' in the treatment of cerebral haemorrhage and 'ketogenic diet' in the treatment of epilepsy.

The chief danger of these little books is that they encourage the habit of cramming.

R. N. C.

TEXTBOOK OF UROLOGY FOR STUDENTS AND PRACTITIONERS.—By D. N. Eisendrath and H. C. Rohnick, M.D. Third Edition. Revised. 1934. J. B. Lippincott Company, Philadelphia and London. Pp. x plus 942, with 700 black and white illustrations and 11 in colour. Price, 42s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 31-8

Docrans Eisendrath and Rohnick are both experts in urology, especially the former who is one of the most known American authorities in this branch of medical science.

It is therefore with great pleasure we welcome the appearance of the third edition of their book.

The first few chapters are devoted to the anatomy and physiology of the genito-urinary tract; laboratory—

methods anaesthesia and description of special instruments used in the treatment of urological conditions.

This part of the book then ends with a chapter on minor technique which contains many useful tips.

Veneral diseases come next and are well described. In the treatment of gonorrhoea, it is noteworthy that the authors do not place as much reliance on the efficacy of irrigation treatment of the urethra, as many surgeons have done in the past and continue to do. After the first few days they advocate the instillation of the silver preparations into the urethra by the patient himself, instead of irrigation.

The newer silver preparations such as neo-protosil, neo-reargon, lomosol, etc., are all described but the authors prefer to use silver nitrate, or argyrol, or protargol. Mercurochrome is stated to be useful in cystitis of non-gonococcal origin only.

Vasotomy and instillation into the vas of argyrol is warmly advocated in resistant cases of gonococcal vesiculitis.

There is an excellent chapter on senile hypertrophy and tumours of the prostate, and at the end of the book all the operative methods of dealing with the enlarged prostate are clearly set forth.

The remainder of the book describes in turn pathological conditions of the kidneys, ureters, bladder, etc., and the authors have found space to include histories and photographs of several interesting anomalies of these organs.

The book is well got up and printed: the coloured plates and photomicrographs being especially good.

Proper names, the commencement of paragraphs, and any sentences, or dicta, which are important, are printed in heavy block type as distinct from the ordinary type of the rest of the printing. This makes the book a little difficult to read, and is our only adverse criticism of an excellent volume.

H. E. M.

SURGICAL DISEASES OF THE CHEST.—By E. A. Graham, A.B., M.D., F.A.C.S., J. J. Singer, M.D., F.A.C.P., and H. C. Ballon, M.D., C.M., F.A.C.S. 1935. Henry Kimpton, London. Pp. 1070. Illustrated with 637 engravings. Price, 65s.

WHEREVER and whenever the subject of chest surgery is brought up the name of Dr. Graham comes instantly to the fore. He is the great pioneer of modern chest surgery, and now in conjunction with Drs. Singer and Ballon he has written a book which will certainly take its place in the forefront of the literature on this subject, and must be considered a classical work of reference.

It is not a volume on the 'surgery of the chest', but as the authors themselves state, it is written from the standpoint of 'the surgical diseases of the chest' which is a very different matter.

The earlier part of the book is devoted to the consideration of the physiology of the thoracic cavity, and the organs contained therein. This is well described and such questions as 'What happens when an open pneumothorax occurs' are clearly answered.

The bibliography is enormous, and the authors must be congratulated on the vast amount of work they have done in compiling it. The spelling of certain words varies in the text, but the reason for this is explained in the preface.

In a work of this nature which is excellent throughout, it seems invidious and it is truly difficult to single out individual chapters for particular mention, but those on the surgical treatment of angina pectoris, valvular heart disease, bronchiectasis, and tumours of the lung are worthy of special mention.

The good results claimed by some other surgeons, notably Hedblom, in the treatment of bronchiectasis by thoracoplasty, are not the experience of the authors of this book.

Whenever non-operative treatment does not effect a considerable amelioration of this condition, and operative interference is decided upon, the caustic pneumectomy of Graham is the method of choice. At

the end of the book there is an interesting description of the chest service section in the Barnes Hospital, St. Louis, Missouri.

The book is very well printed, but is large and extremely heavy, so we suggest for the consideration of the authors that future editions should be divided into two if not three volumes.

H. E. M.

A TEXTBOOK OF PATHOLOGY.—Edited by E. T. Bell, M.D. Second Edition. 1935. Henry Kimpton, London. Pp. 767, illustrated with 364 engravings and 2 coloured plates. Price, 37s. 6d.

IN the second edition of this book which has deservedly been well received by the medical profession the text has been thoroughly revised and brought abreast of current medical literature. The various topics are discussed more fully and a large amount of new material has been introduced. A new chapter on diseases of the bones and joints has been added and more references to the literature are given at the end of each section. These references are particularly useful in the selection of original articles in any particular subject in which the reader is interested. This is a remarkably useful publication, the pathology of each disease is fully described and an interest is maintained throughout in clinical conditions. Many excellent photographs and line drawings illuminate the text. Altogether this is the type of work which one would expect when each section is written by contributors who have made a special study of the subject and the whole book is so well edited that the subject becomes alive and interesting. It is a work we can confidently recommend to the medical student and medical practitioner.

C. L. P.

MEDICAL BACTERIOLOGY: DESCRIPTIVE AND APPLIED INCLUDING ELEMENTARY HELMINTHOLOGY.—By L. E. H. Whitby, C.V.O., M.A., M.D. (Camb.), F.R.C.P. (Lond.), D.P.H. Second Edition. 1934. J. and A. Churchill Limited, London. Pp. ix plus 338, with 74 illustrations. Price, 10s. 6d.

THE second edition of this book maintains the characters of the original. The subject-matter is presented from the same aspect, namely the description of certain elementary and essential bacteriological facts and the application of these to practical medicine. Controversial and other subjects are dealt with briefly in small print. There is a great deal of excellent and useful information contained in this book and it is arranged in such a manner that the elementary student can read through the various chapters and obtain a sound working knowledge of the subject without being confused by different theories and discussions on more highly technical subjects. The book is divided into two parts, part one deals with descriptive bacteriology and part two with applied bacteriology, a chapter of 13 pages devoted to protozoal diseases and one of 11 pages for helminthic infections are included. It is not only impossible to deal adequately with such subjects in the confines of small chapters but it is irrational to continue the custom of including these two subjects in books dealing mainly with bacteriology. We are fully aware of the convenience of doing this but would suggest that a more appropriate name for such books should be 'parasitology'.

As a general rule the old bacterial nomenclature has been adhered to and the new nomenclature shown in brackets when a particular organism is described. We would prefer this order to have been reversed and the new nomenclature which is gradually being adopted almost universally to have been introduced, particularly as this is a type of book which is intended primarily for medical students. Turning to the sections of particular importance in the tropics we find many statements which experience in India does not support. Under the section dealing with *V. cholerae* on page 143,

when dealing with serological reactions, there is a statement that agglutinins up to a titre of 1 in 1,000 occur during the disease and carriers also give a positive agglutination test. This statement will tend to leave an impression on the mind of the student of the importance of the presence of agglutinins in diagnosis of cholera whereas actually it is only in convalescence that we find agglutinins in the blood and it is only in that type of carrier who has had the disease that we find agglutinins. Again under diarrhoea on page 273 the student is advised that the examination of the faeces may be supplemented by testing the blood serum for *Widal's* reaction. This is a type of advice which leaves the reader uncertain as to what is meant and in fact in many places this term '*Widal's* reaction' is used without proper definition. These are all the faults that we can find in a book which is eminently suited for the needs of the medical student and which is an excellent introduction to a more advanced study of bacteriology.

C. L. P.

HUMAN PHYSIOLOGY.—By F. R. Winton, M.D., and L. E. Bayliss, Ph.D. Second Edition. 1935. J. and A. Churchill Limited, London. Pp. xvi plus 627. Illustrated with 221 text-figures. Price, 15s.

This book although it is only five years old has now reached its second edition—a fact which tends to prejudice the reviewer in its favour. The academic teacher of to-day, with the curriculum as it is, knows that it is no easy task to instruct the medical student in physiology, keeping in mind that the study is not an end in itself and that only some fifteen months can be devoted to it. The subject, however, as it is set out in these pages should prove a good guide to the teacher and a well-balanced and interesting treatise to the student. The arrangement of the chapters is instructive. Hitherto most books on physiology have devoted a chapter to the biophysics, biochemistry and physiology of the most elementary phenomena of life. Such a chapter is often interesting but usually does not interest the student fretting to go into the wards. This information is or should be given to the student in his preliminary biological course. The authors however commence the book with a discussion of the physiology of muscular activity in its broad aspects. This chapter is interesting and should tempt even the layman.

Then follow chapters on circulation, the blood, respiration, digestion and nutrition, etc. The detailed mechanism of muscle chemistry and renal secretion are taken up later. The final chapters of the book are devoted to the organs or systems which are primarily concerned in the co-ordination and integration of the body as a whole, namely the central nervous system including the special senses and the endocrine organs. The book is not too large for the medical student and yet it touches on all the recent advances. The intimate chemical changes associated with muscle activity are shortly and clearly written. A page or two are devoted to some of the newer work on the rôle of acetyl choline and adrenalin (or adrenergic substance) in the mediation of the transmission of the nerve impulses across synapses and possibly, in the case of acetyl choline, at all myoneural junctions. The description of conditioned reflexes is interesting, particularly the condition of experimental neurasthenia which can be induced and the effect of drugs on these reflexes. It is doubtful if the page and footnote on aphasia is adequate to explain the full significance of Head's conceptions. The few lines however while touching on the trend of modern psychology should be sufficient to stimulate the intelligent student to seek special sources of knowledge on this subject and avoid the too simple ideas which the old stereotyped diagrams engendered.

The book is calculated to make the student think and can be thoroughly recommended as one to keep with him during his clinical studies.

H. E. C. W.

PHYSIOLOGY IN HEALTH AND DISEASE.—By C. J. Wiggers, M.D. 1935. Henry Kimpton, London. Pp. xxvii plus 1156, with 182 engravings. Price, 42s.

This textbook is something new; here is a departure from the plan upon which most of the textbooks on physiology with which we are familiar are built, or perhaps it would be better to regard this book as a scientific approach to the understanding of functional disturbances in man. The author in the preface states 'This physiological manner of clinical approach makes it incumbent upon teachers of medical physiology to give greater regard to its correlation with clinical medicine and surgery; but this must be accomplished without sacrificing considerations of the biophysical, biochemical and mathematical aspects of physiology as a pure science'. After twenty-five years of teaching in three prominent medical schools, the author has experimented with a plan of teaching that (1) stresses the application of pure sciences to physiology, (2) inculcates general principles of physiology, (3) outlines and surveys the functions of various tissues, organs and systems and (4) correlates physiological alternations produced experimentally with aberrant manifestations illustrated on patients. This is a comprehensive plan of instruction and because of the lack of a single textbook which covers the subject-matter the author has produced this book. By judicious curtailment of certain features generally included in standard textbooks of physiology such as extensive anatomical and histological discussions and the condensation of other portions, the author has been able to introduce many new topics of physiological importance which are the attractive features of the book. Further by dividing the book into ten sections and sixty chapters, each chapter covering a complete topic, the author has succeeded in ensuring easy availability of essential facts. Each chapter is further liberally divided and subdivided by distinctive types which permit an easy outlining of information, and the text throughout is illustrated by numerous charts, graphs and figures mostly new, and many problems are presented in a strikingly graphic form. An unusually extensive bibliography is incorporated in the book, a list of important references together with explanatory notes at the end of each reference is given in every chapter.

The book is a mine of information, contains a critical account of the physiological principles and is full of brilliant suggestions, useful comments and interpretations that appeal and interest. The time has certainly arrived when a book such as this will prove most interesting reading for the post-graduate student of medical science and we commend it to all who would consider themselves advanced or modern clinicians. It presents the fundamental characteristics of normal functioning and shows how variations from the normal are produced and is a work which should provide stimulus and new thought both for teachers and students.

C. L. P.

TOXICOLOGY. (CATECHISM SERIES).—By Andrew Allison, M.B., Ch.B., B.Sc., D.P.H., F.R.F.P.S. (Glas.). Third Edition. 1935. E. and S. Livingstone, Edinburgh. Pp. 83. Price, 1s. 6d. Postage, 2d.

THE Catechism Series is undoubtedly to the student mind a godsend. From the general point of view of medical education this view could be questioned, however, as the knowledge purveyed is extremely condensed and tends to lack interest and often perspective.

Certain subjects, however, are especially amenable to such treatment, notably this one. It is not a subject that the medical man is often called upon to deal with, yet the information must be ready to hand as quick action is essential in cases of poisoning.

This little book is written in such a way that it can be easily memorized by those with good memories and

equally easily consulted by those without. It can be confidently recommended both for those in practise and for experts as a number of useful details are given. It should be noted that the price is approximately only a rupee.

H. E. C. W.

ELECTROTHERAPY AND LIGHT THERAPY.—By R. Kovacs, M.D. Second Edition. 1935. Henry Kimpton, London. Pp. 696. Illustrated with 263 engravings and a colour plate. Price, 35s.

THE popularity of this work is shown by the fact that this second edition has appeared within three years of the original one.

The popularity is well deserved. Dr. Kovács is one of the leading practitioners and teachers in the subject of electrotherapeutics in America and every page bears the stamp of authority.

The first part of the book, comprising four chapters, deals with elementary principles of physics and electricity.

The second part deals with general electrotherapy and electrodiagnosis. No praise is too high for this section. Its treatment is masterly. Such new subjects as short- and ultra-short-wave diathermy are included, as is the production of artificial pyrexia by diathermic methods.

The third part deals with light therapy—a well balanced account, completely lacking in the excessive enthusiasm of some writers who find a plea for light therapy for conditions ranging from a common cold to inoperable carcinoma.

The last section of the book, a considerable one, deals with the application and more practical aspects of both the preceding sections.

This is primarily a work for the specialist in electrotherapy or general physicians who do some practice in the subject. As such no praise is too high for it.

It will also find a place on the shelves (and we hope, sometimes, the desks) of other practitioners and students to show them what can be done by modern electrotherapeutic methods, and also occasionally to warn them as to their limitations.

G. G.

A TEXTBOOK ON THE NURSING AND DISEASES OF SICK CHILDREN FOR NURSES.—By various authors. Edited by A. Moncrieff, M.D., F.R.C.P. (Lond.). Second Edition. 1935. H. K. Lewis and Company Limited, London. Pp. xiv plus 583, with 112 illustrations. Price, 15s.

Nursing and Diseases of Sick Children is a textbook for nurses and is designed to cover the syllabus for the certificate for sick children's nurses issued by the General Nursing Council of England and Wales. It is the work of several medical men each an expert in his subject and the whole has been discussed with members of the nursing profession to ensure that adequate emphasis is given to the practical details of nursing.

The book is divided into two parts: part I dealing with the care and nursing of the child and part II with diseases of children. Part I is further divided into three sections relating respectively to the general care of normal and sick children, general medical nursing of sick children and general surgical nursing. Part II is a concise yet remarkably complete account of the ills to which the child is liable. It more than covers the nursing syllabus and should prove a standard reference book for members of the nursing profession. Tropical diseases have unfortunately no place in the volume. There are several useful appendices including one on drugs and their action, another on breathing exercises after tonsillectomy and one on speech training after cleft-palate operation.

Hospitals for sick children and even children's wards in general hospitals are conspicuously absent in India and the training of nurses in this aspect of their

profession is very inadequate. This is the more regrettable since it is just in this field, where the patient can give little help by describing symptoms, that the nurse trained to observe and record can be of most value to the doctor and of most comfort to the parent. 'The best nurse is not the one who knows most but the one who observes best'. This textbook supplies all that the nurse can want not only of knowledge of children's diseases but for the nursing and observation of children. It will be invaluable to her and to her teachers in the daily routine of the child's sick room. *Nursing and Diseases of Sick Children* is a standard book on a subject rarely written on by experts and it can be cordially recommended.

J. M. O.

TABLE OF INCOMPATIBLES.—By Dr. R. N. Worrall. 1935. John Bale, Sons and Danielsson Limited, London. Price, 1s. 6d.

THIS is a table printed on a thick sheet of paper about 17 inches by 16 inches. The names of 56 important preparations are printed vertically on the top and bottom of vertical lines. The same names in the same alphabetical order are printed horizontally on the two ends of horizontal lines. The points of intersection of these central lines are blank if the preparations are compatible. There is a black dot if the preparations are incompatible, and there are circles if they are not strictly compatible. Some of the preparations which are more or less poisonous are underlined in order to draw the special attention of the readers. The prescriber or dispenser is thus enabled to see at a glance the suitability of a particular combination of drugs and is saved the time and trouble of racking his brains or hunting through some textbook. On the opposite side of the sheet are given lists of some reducing and oxidizing agents, some acid and alkaline preparations and also some hints under the heading of miscellaneous reminders. A table like this could not be made exhaustive within a limited space but it will certainly prove useful to a busy prescriber or dispenser. The utility of the table could perhaps be increased by printing all the information on one side of the sheet.

S. G.

THEORY AND PRACTICE OF NURSING.—By M. A. Gullan, S.R.N. Fourth Edition. 1935. H. K. Lewis and Company, Limited. Pp. xvi plus 259, with 3 coloured illustrations. Price, 9s.

THE fourth edition of this book has been thoroughly revised and brought up to date and several additions have been made which will make it of greater value to nurses.

A scale of constituent and caloric values per ounce of representative foods has been introduced, which should arouse a common-sense interest in the nurse regarding food values, both in quantity and quality, in a normal diet. The value of the blank leaves, interspersed in various chapters, cannot be too highly emphasized, as the nurse in training can add brief notes of her practical experience bearing on the subject, which will make the book especially useful to her.

It is in every way to be recommended to nurses in training in the United Kingdom.

M. A.

MEDICAL CASE-TAKING.—By Bidhu Bhushan Pal, L.M.S. 1935. Published by Indu Bhushan Pal, M.B., 1/1, Ananda Chandra Roy Street, Dacca. Pp. xi plus 191. Price, Rs. 2-8 (Cloth bound). Rs. 2 (Paper Cover)

THE importance of a methodical examination of patients cannot be overestimated. It forms the groundwork of learning in all medical subjects. In this book the author has endeavoured to compile in a small space the method of examining patients and to teach the student what he should look for. The book will prove useful to a student while attending his clinical lectures. Certain sections are however too short. A

beginner will not learn in this book the technique of blood pressure reading, blood counting and staining methods, etc. Only the rough Tallqvist's method which usually gives misleading figures of haemoglobin estimation has been referred to. Statements such as 'frontal

headache is due to dyspepsia, occipital...constipation, vertical...anæmia or debility' cannot be commended.

The book has no illustrations nor index. There are many printing mistakes.

R. N. C.

Abstract from Report

ANNUAL REPORT OF THE ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH FOR THE YEAR 1931

As this is the first Annual Report of the Institute, it will not be out of place to recapitulate shortly the ideas and events which led to the conception of an All-India Institute of Hygiene, to its construction, and finally to its formal opening on 30th December, 1932.

Public health policy in India started with the taking over of the administration of British India by the Crown in 1857. The high mortalities among British and Indian troops and in the civil population attracted the attention of Parliament and in 1860 a Royal Commission visited India and made recommendations for the improvement of health and sanitary conditions in India. This Commission recommended that sanitary commissions should be appointed in the major provinces of Madras, Bengal and Bombay. These commissions were established and for some years did good work. Departmental jealousies and other causes however led to their gradual emasculation and by 1900 they had been reduced to one officer, the sanitary commissioner, who had little or no staff and whose duties were largely confined to inspecting vaccinations. The advent of plague in 1896 led to a general awakening of everyone's responsibilities in the matter of health and prevention of disease, and in 1912 the Government of India formulated an important declaration of sanitary policy, establishing research on a sound basis, and giving grants to local governments for the augmentation of their sanitary staff, both central and provincial. The Government of India in a resolution insisted that candidates for assistant directorships of public health should have a British Diploma of Public Health. Health officers of first class towns were required to have a registrable qualification and a British Diploma of Public Health. In this resolution they stated, 'The necessity for a British Diploma of Public Health will however only be temporary, as the Government of India trust that it may be possible to waive the second restriction as soon as arrangements can be made in India which will enable Indians trained in this country to become health officers of the first class'.

Provincial governments took up the question of providing such training, and qualifications in public health and higher diplomas and degrees demanding specific courses of training were initiated by the universities of Bombay, Madras, Calcutta and Lucknow. These, however, naturally retained a provincial outlook. The conception of providing courses in hygiene on a wider basis originated with Sir Leonard Rogers who in 1914 conceived the idea of establishing institutes in India for post-graduate study in tropical medicine and hygiene. Sir Leonard's first proposal was that there should be a School of Tropical Medicine in Calcutta, and an Institute of Hygiene in Bombay, and that both of these might be on an all-India basis. Various circumstances and considerations prevented these views from coming to fruition, but it was chiefly owing to Sir Leonard Rogers' perseverance and enthusiasm and to the generosity of the Governments of India and Bengal and various private benefactions, that in 1920 the Calcutta School of Tropical Medicine and Hygiene, which combined teaching and research in both tropical medicine and hygiene, was opened. A Professorship in Hygiene was established, and a course of instruction arranged in the School for the Diploma of Public

Health of the Calcutta University. There were obvious limitations to the scope and outlook of this arrangement. However enthusiastic one man may be, there are now so many aspects of public health both of temperate and tropical climates, each of which is rapidly developing and requires the full attention of a single worker and teacher, that it is impossible for a single person to combine the qualities or to find the time necessary to assimilate, digest and teach the diverse subjects comprising the entity known as modern public health. Workers highly trained in general hygiene and specialists in some particular branch are needed in India, and as time goes on and public health policy broadens and expands in all Indian provinces, such workers trained in Indian needs and with Indian experience will be more and more required. Major-General Sir J. D. Graham, the then Public Health Commissioner with the Government of India, said in his Annual Report for 1925 (Section VIII):—

*'The need of providing training for public health workers.—*Certain conclusions have been forced upon me after careful study of the position over the last few years. It is becoming increasingly evident that a considerable section of the Indian community is thinking seriously on these public health problems'.

'This is a work which has to be done for the benefit of Indians. To be effective it must carry conviction and establish its position against immemorial conservatism and tradition, it must therefore be done by Indians. It presents a grand and unlimited field for public health workers, but it is well to recognize that the improvement cannot be achieved when the expert labourers are too few in number, that these cannot be increased to the requisite number without a careful system of specialized training in institutes or schools devoted to public health teaching and research, and that cannot be done without adequate financial support. The need for such training of Indian personnel has been advocated for the last two decades by our expert hygienists and research workers in India. It has often been represented, and not without justice, that scientific knowledge in regard to the prevention of certain communicable diseases has far outstripped its application in the field. It is with such a personnel that the practical application must finally rest'. As head of the Calcutta School of Tropical Medicine and Hygiene, Major-General Sir John Megaw arrived at similar views, which were expressed from time to time in the annual reports of the School. Dr. W. S. Carter, Associate Director of the Rockefeller Foundation, in his periodic tours of India and the Far East, met General Megaw and General Graham on various occasions and became deeply impressed with the necessity for establishing an all-India institute of hygiene. Much of the teaching in basic subjects, such as bacteriology and protozoology, for the Diploma of Public Health is similar to that for the Diploma of Tropical Medicine, and as this was being taught in the School of Tropical Medicine, Dr. Carter at once grasped the obvious advantages of Calcutta as a location for an all-India institute, and of a site close to the Calcutta School of Tropical Medicine, where the basic subjects would continue to be taught. It would thus be unnecessary to duplicate these courses, and at the same time the institute would deal with purely public health subjects especially related to Indian requirements. As a result of discussion with General Megaw and others,

Dr. Carter, on behalf of the Rockefeller Foundation, addressed the Government of India in terms embodying these proposals, offering to provide the cost of acquiring the site selected, and to build and equip an all-India institute of hygiene and public health, and further asking for the Government of India's assurance that they would meet the recurring cost of staff and maintenance after the building was handed over to them. The Government of India gratefully accepted this munificent offer and negotiations for the acquisition of the site were commenced. This was acquired finally in July 1930, and the site was cleared and building commenced in September. A constructional committee composed of the Public Health Commissioner with the Government of India, the Surgeon-General with the Government of Bengal, the Chief Engineer with the Government of Bengal, the Chairman of the Calcutta Improvement Trust, and the Accountant-General, Bengal, was appointed to arrange for the construction of the building. Lieutenant-Colonel A. D. Stewart, Professor of Hygiene in the Calcutta School of Tropical Medicine, was appointed Director-designate of the new Institute, and Lieutenant-Colonel A. A. E. Baptist, Assistant Director, to superintend the actual details of construction and equipment.

The building was completed early in 1932 and was formally opened by H. E. Sir John Anderson, Governor of Bengal, H. E. the Viceroy being unable to perform the function owing to indisposition.

The building practically adjoins the School of Tropical Medicine with which it harmonizes in design and appearance.

The plan is based on the 'unit room' system, the unit room being 25 by 21 feet. The building is four storied and is E-shaped, the long limb being in the centre. Six sections can be accommodated, viz, (1) Public Health Administration, (2) Sanitary Engineering, (3) Vital Statistics and Epidemiology, (4) Biochemistry and Nutrition, (5) Malariology and Rural Hygiene, and (6) Maternity and Child Welfare and School Hygiene. Each section has one unit room for the head of the section and two unit rooms for the workers. The working sections are placed in the central limb of the building, facing north with an excellent and unimpeded north light. In the west block are placed the administrative rooms, lecture theatre, practical class rooms, museum, and a large auditorium to seat 200 people. The eastern limb houses store rooms, common room, and lunch room for students, spare working rooms and lavatories, while a separate annexe provides for an animal room on each floor. The library is in the centre block on the top floor. Three unit rooms on each floor and the library and reading room are provided with conditioned air during the hot months of the year. The head of each section has a cooled unit room and in addition there is a spare cooled unit room on each floor where workers on that floor may work in comfort, or engage in any special work requiring a cooled atmosphere.

Owing to the sudden financial crisis at the end of 1931, the Government of India found themselves unable to shoulder the financial burden of Rs. 3,50,000 per annum which the six sections required and decided to allot a sum of Rs. 2,00,000 per annum, agreeing to restore the original sum when monetary conditions improved. Accordingly only four sections were opened, the sections of Sanitary Engineering and Maternity and Child Welfare remaining in abeyance. The committees of the Countess of Dufferin Fund however and of the Red Cross Association of India, realizing the importance of the section of Maternity and Child Welfare and especially the necessity for providing post-graduate instruction in the work not only for men but especially for women graduates, agreed to lend the services of Dr. Jean M. Orkney to initiate the section and also to grant the necessary funds to finance the section.

Functions and purpose of the Institute.—It has often been stated and with a considerable degree of truth, that scientific research work and knowledge of disease

in India has far outstripped its practical application throughout the country. How to achieve this in practice is one of the most difficult and fundamental difficulties in India. To apply scientific knowledge to prevention of disease requires at the beginning a desire for health on the part of the whole population, both as individuals and as a community. Knowledge acquired by such a desire must be put into daily and constant practice by everyone, and everyone must be prepared to pay something towards concerted action. Local bodies must be actuated by the same desire to improve the environmental conditions of the villages, towns and districts under their charge, and must be furnished with the necessary powers and necessary funds. They must however have the guidance of an expert sanitary officer who has under his control a sufficient and trained staff. Local bodies in their turn must be guided and controlled and when necessary compelled by a competent department of health of the local government, whose duties and powers will have been laid down clearly by the legislature. All this requires wise and farsighted statesmanship and legislation, and calls for the exercise of the highest and best features of individual and national character. It demands a certain status of economic development of the people, and a certain standard of education throughout, and above all an understanding of the value and the possibilities of human existence and a constant desire for improvement and betterment. It is quite obvious that the establishment of one institute cannot do all this but it can play an important part. While it may later have wider spheres, at first it must take on the important rôle of training staff who will later play the important part of improving environmental conditions throughout India, and of advising local bodies, and educating the people in the principles and practice of health ideals. This training will always be one of the main tasks of the Institute and every endeavour will be made to make this training as good as possible, keeping in view the needs and problems of the different provinces of India. In this training the School of Tropical Medicine co-operates to the fullest extent and the subjects of Bacteriology, Protozoology, Entomology and Public Health Laboratory Practice are taught by the staff of the School. Though the School of Tropical Medicine is a provincial institution under the Government of Bengal, it has never really been provincial in training or outlook, and it is in the interest of the whole of India that the teaching in the School should remain at a high standard of excellence.

Post-graduate qualifications such as the Diploma of Public Health or B.Sc. in Sanitary Science are required for most health appointments. The University of Calcutta has for some years given a Diploma of Public Health which in common with such qualifications granted by other Indian universities is accepted for many of the health appointments in India. The School of Tropical Medicine is already affiliated to the University of Calcutta and the Institute will shortly also be affiliated. Most of the post-graduates under training proceed to take the Diploma of Public Health of the Calcutta University. This is open only to graduates, however, and it is recognized that there are many workers in public health in India, both in military and civil employ, and in Indian States, who would benefit greatly by a thorough training in public health, and who could proceed to a career in public health and in sanitary departments if they also possessed a diploma in public health. This question was very carefully considered by the Government of India and the Government of Bengal, and it was agreed that a Diploma in Public Health and Hygiene should be granted by the Faculty of Tropical Medicine and Hygiene of Bengal. This Diploma will be essentially of the same standard as the D. P. H. of the Calcutta University. Candidates for training for this Diploma will be specially selected. They may be sub-assistant surgeons who have done health work or they may be holders of medical diplomas who have shown special

aptitude in health work or research, or military assistant surgeons not holding a university degree. Applications for this course are carefully considered by the selection committee and only such applicants accepted as are considered suitable by education and achievement, to benefit by the course.

The regulations for the D. P. H. of Indian universities are mostly based on those of the General Medical Council of Great Britain. The training for the D. P. H. in Great Britain is specially designed for training and turning out doctors fitted to be assistant medical officers of health in the United Kingdom. Public health conditions and public health administration are peculiar to each country and it is obvious that more and more of our health officers should be trained in India, though the broadening and educative value of study and travel abroad will always be desirable. The work of an assistant medical officer of health in Great Britain is largely confined to urban areas, as over 80 per cent of the population in the United Kingdom live in fairly large towns. It is natural that his training in practical public health administration should be done in towns, and the regulations of the General Medical Council insist on this. In India it is different as most of the population live in rural areas. The regulations for the D. P. H. in India however being based on those of the General Medical Council still insist on training in methods of public health administration in a large town. While this is undoubtedly both necessary and desirable the necessity for practical training in rural health problems has been overlooked or not sufficiently stressed. One reason for this has been the lack of well-organized rural health organizations where up-to-date methods dealing with the problems of rural areas in India could be demonstrated. I think the University regulations in this respect need reconsideration, but until we have better organizations in rural areas it may be better to leave this question as it is at present and to demonstrate the present problems of rural areas as they now exist. A malaria research station in a rural area is a necessity for a teaching institution and while we have established the nucleus of such a station near Calcutta, it needs enlarging and putting on a better basis.

The Calcutta University has recently instituted a Doctorate of Science (Public Health) which will be a higher degree open to those holding the D. P. H. and will be obtainable after a year's study and research in some special subject in public health. A thesis on this subject will be submitted and a higher examination in the general aspect of public health also taken. Short courses of post-graduate instruction in special subjects for public health are also being arranged. These will be intended for public health workers in India desiring to refresh their knowledge in special subjects such as statistics, nutrition, malariology, etc. Such courses will be of about 3 months' duration, and it is hoped will be taken advantage of by members of provincial public health staffs and others.

Mention has been made of the section of Maternity and Child Welfare. There is a great need in India for more doctors specially trained in maternity and child welfare work. This work all over India has grown up sporadically without much forethought, planning or co-ordination, and mostly by voluntary agencies who deserve great credit for initiating the work. The need for trained women graduates who could take charge of the work and direct and develop it on proper lines has been felt, and hitherto the only means of obtaining such training was to proceed to London or elsewhere. The Faculty of Tropical Medicine and Hygiene of Bengal in 1933 decided to create a Diploma in Maternity and Child Welfare to be given to women graduates after examination and a course of training in the Institute. One course has already been held in 1933 and another is now under progress.

Research and investigation.—The problem of cholera is one of the most pressing in India and it is fitting that the Institute during the first year of its existence

should have devoted considerable attention to this disease.

The study of conditions making for endemicity or epidemicity is obviously one of extreme interest and importance not only to India but to the outside world. Since the cause of cholera is known, it was natural that the causes of endemicity and epidemicity should be sought in the vibrio itself. Agglutination by a high-titre serum as a fundamental diagnostic property of a 'true' cholera vibrio was probably first laid down by Kolle and Gottschlich in 1903, and as late as 1933 was accepted by the Office International as one of the principal criteria in the recognition of the true cholera vibrio. It is to be noted however that Kolle and Gottschlich themselves found many discrepancies, but they attributed such irregularities to faults in plating technique and to contaminations. Later results however showed that non-agglutinating vibrios were found under a variety of conditions which demanded closer study and interpretation. d'Herelle and others found such non-agglutinating vibrios in pilgrims at El Tor returning from the Hedjaz pilgrimage. d'Herelle was of opinion that as these vibrios had never been incriminated with outbreaks of epidemic cholera the persons carrying them were therefore harmless. Tomb and Maïtra and Brahmachari in India working in endemic areas found that the number of such non-agglutinating carriers progressed in number during the cholera season and diminished as the season declined. In 1933 Pasricha made a very definite contribution to the problem by finding that, in the annual cholera season in Calcutta, the great majority of typical cholera cases at the beginning of the epidemic were non-agglutinating, that at the height of the epidemic agglutinating strains were universal, and that non-agglutinators again made their appearance at the decline of the season. This has made us revise many of our ideas as to the rôle of the non-agglutinating vibrio. Doorenbos's classification of endemic and epidemic types of vibrios does not, at least at present, seem justified. The whole carrier question has assumed great importance and a voluminous literature has developed in relation to it. It became obvious that there were a series of puzzling problems of a diverse nature relating to cholera which needed co-ordinated investigation and in 1931 proposals were made by the Indian Research Fund Association for the establishment of a Cholera Commission which would investigate the various aspects of the problem in India in a carefully co-ordinated manner. Unfortunately the financial crisis abruptly stopped this scheme, though research on various aspects of cholera still continued in India. The urgency of some co-ordinated investigation into certain aspects however was again brought forward in 1932 by certain findings in Syria where healthy persons coming from Iraq were found to be carrying agglutinating vibrios, and this despite the fact that many of them not only had been inoculated, but came from areas which were not infected with cholera. What was the significance and danger of such people and such vibrios? The matter, being one of international importance, was discussed at various meetings of the Permanent Committee of the Office International d'Hygiène Publique. At the May meeting of 1933 which I attended as the representative of the Government of India, the matter was discussed fully and I conveyed the views arrived at to the Government of India. These were that the fundamental problems of vibrio character under conditions of epidemicity and endemicity could only be studied in India, and the same applied to the carrier problem. The Office therefore requested that the Government of India might start investigations into the particular points. In his note to the delegate from British India, the President of the Permanent Committee particularized the following points for investigation in India:—

(a) Do the vibrios in the intestine either of convalescent or healthy carriers properly so called, preserve or do they lose their pathogenicity?

(b) In what way is the virus of cholera maintained in the endemic regions during inter-epidemic periods, is it by means of one or other of these two categories of carriers or by both of them or otherwise?

(c) In an endemic region do vibrios in the intestine of a carrier which have been deprived of their virulence, recover their virulence and become the cause of the outbreak of an epidemic of cholera?

(d) In epidemic regions, is the rôle of convalescent or of healthy carriers the same as in endemic regions?

(e) Is it possible for a healthy carrier in an epidemic region to be the origin of a case of cholera?

(f) Has it been found possible to obtain a rapid sterilization of cholera carriers and, if so, by what means?

The Permanent Committee of the Office at this meeting passed the following resolution:—'It would be desirable that a technical Research Committee should be formed in British India in order to elucidate some obscure points in the cholera problem, among others the pathogenic significance of vibrio disseminated by carriers, according to their place of origin'.

The Government of India referred this communication to the Indian Research Fund Association which, having already decided on the formation of a Cholera Commission in 1931, naturally gave the communication the most careful consideration. Though a Cholera Commission had not actually been formed, important work was being carried on in India into the phenomena associated with cholera plague in Patna under Dr. Asheshov, in Shillong under Lieutenant-Colonel Morison and in Calcutta under Captain Pasricha. Important chemical investigations into the structure of the cholera vibrio had also been commenced by Dr. Linton at the All-India Institute of Hygiene in Calcutta. In addition to the Working Committee on Cholera, the Scientific Advisory Board of the Indian Research Fund Association formed also an Advisory Committee on Cholera with the object of co-ordinating all the work to be done on cholera in India and it asked this Advisory Committee to frame proposals for work which would, if thought necessary and desirable, embody the proposals put forward by the Office. The Governing Body of the Indian Research Fund Association eventually agreed to proposals put up by the Cholera Advisory Committee on the lines of a scheme outlined by Lieutenant-Colonel Taylor. This enquiry is located mainly at the All-India Institute of Hygiene in Calcutta and comprises a field section in an endemic area under Dr. Lal, a bacteriological section in the School of Tropical Medicine and All-India Institute of Hygiene under Captain Pasricha, a biochemical section under Dr. Linton in the All-India Institute of Hygiene and a clinical enquiry under Captain Pasricha at the School of Tropical Medicine. A section at the Central Research Institute under the Director is also correlated with the enquiry, and the enquiries into bacteriophage at Shillong and Madras are also within the purview of the Advisory Committee.

One of the main objects of the enquiry is to collect vibrios from cases of cholera, convalescents, and carriers (so called). These vibrios are thus of known origin and related to definite happenings in the field. These vibrios are first isolated, and then passed on to Captain Pasricha's section for further investigation as to the agglutinability and biochemical reactions. Particular and selected strains are then examined for their reactions to the various types of phage, and passed on to Dr. Linton for determination of their structure, and to the Director, Central Research Institute, for particular serological examinations, particularly with regard to their antigenic structure and their reactions to O and H agglutinating sera. (Dried O antigen has been suggested as a reliable differentiating agglutination reaction.)

These results are then pooled and correlated with the relationships to the original happenings in the field. In this manner it is hoped to correlate particular types of vibrio with particular happenings in the field endemic

area. The problem of endemicity is also being investigated by statistical methods in the section of Epidemiology and Vital Statistics of the Institute.

The enquiry has not been established long enough to give pronouncements of definite value. Of particular interest we think is the grouping of vibrios suggested by Dr. Linton as the result of his studies. The vibrios fall into 6 groups according to the individual combinations of protein and carbohydrate. It is of interest to note that the large proportion of vibrios isolated from cholera cases fall into group I and that the El Tor vibrios which are agglutinable but apparently non-pathogenic are associated with the ordinary cholera vibrio by their carbohydrate (which may account for their agglutinability) but to water vibrios by their protein (which may account for their non-pathogenicity). Personally I regard Dr. Linton's work as a contribution of the greatest interest and importance to the classification of cholera vibrios and it is with some expectation that we look forward to seeing if the vibrios isolated from cases and carriers (carriers both associated with transference of disease, and those not so) will fall into Dr. Linton's groups with any consistency. A reference to Dr. Lal's report will show that a study of endemicity on statistical lines is likely to elucidate very interesting facts. Endemicity of cholera is by no means uniform in Bengal, or even in the district of 24-Parganas which has a very high endemic figure. The analyses and investigations in this direction however have not gone far enough yet to make definite pronouncements.

I would draw attention to some features of interest in the report on the section of Biochemistry and Nutrition. This section was opened in March 1933 and a large amount of time has naturally had to be expended in organizing and equipping the section. It will be noted that Dr. Wilson regards two lines of work as of fundamental importance, namely, an accurate knowledge of the basic composition (including vitamins) of all the ordinary Indian foodstuffs, and diet surveys of the different classes and communities. Without this preliminary information, it will be impossible to criticize or to offer suggestions for improving the nutrition of the community. In this he is in agreement with Sir Robert McCarrison whose ambition it was to establish a nutritional institute in India, one of the main objects of which would be to conduct work along these two lines. The idea of a nutritional institute for India has unfortunately not yet fructified. Sir Robert McCarrison is on the point of retirement. On the appointment of his successor, early opportunity will be taken to discuss the work to be carried on at the Nutritional Institute at Coonoor and at the All-India Institute of Hygiene so that co-operation may be maintained, work rendered complementary, and unnecessary overlapping if possible avoided.

The Department of Malariology and Rural Hygiene under Dr. Krishnan has now been equipped with all the necessary equipment both field and laboratory for demonstrating methods of malarial investigation and control to post-graduates. This is of great importance as students proceeding to the D. P. H. should be fully acquainted with methods of investigation and control of the principal disease in India, *viz.* malaria. It is necessary therefore to have a field station attached to the Institute and it is hoped that this will soon be established. Dr. Krishnan has continued his interesting work on the relationships of the reticulo-endothelial system to malaria and blackwater fever. Hæmoglobinuria is apparently the result of two factors, the destruction of a large number of infected red cells by the malarial parasite, and the shedding of hæmoglobin products into the blood from these cells owing to the absence of a sufficient number of phagocytic reticulo-endothelial cells. Hæmoglobinuric fever is thus associated with questions of immunity or tolerance to the malarial parasite, with the production of intense infection, with treatment with quinine and with the mechanism of production and action of reticulo-

endothelial phagocytes. Dr. Krishnan is at present investigating these points, especially with a view to treatment, in monkeys infected with malaria; and it is hoped valuable results may emerge which will be applicable to blackwater fever in human beings. The department has also given useful assistance to outside bodies.

I have already noted that the department of Maternity and Child Welfare was kept in abeyance by the Government of India owing to financial stringency, but that the Countess of Dufferin's Fund and the Red Cross had kindly come forward and offered to start the section. This offer was gratefully accepted and Dr. Orkney has directed and controlled the section during the year. The initiation of a Diploma in Maternity and Child Welfare by the Faculty of Tropical Medicine and Hygiene of Bengal has already been mentioned, and one of the main reasons for the Dufferin Fund Committee in partially financing this section was to provide facilities for training post-graduates in this diploma. An essential part of such training is district work and facilities for this have been provided by the establishment of a maternity and child welfare clinic in Ward 8 which is close to the Institute. This clinic is popular and doing good work in the Ward; it is assisted by grants of money and milk from the Calcutta Corporation and it has been possible to extend its activities largely, and to add a nursery school and a nucleus of school medical inspection by a grant from the Calcutta Health Week Committee, to which we are naturally very indebted and grateful.

Tuberculosis Research under the Indian Research Fund Association.—This enquiry, under the auspices of the Indian Research Fund Association and financed by it, has been carried on by Dr. A. C. Ukil since 1928, and in 1932 accommodation was provided for it in the Institute.

Dr. Ukil has shown that the remarkable absence of tuberculosis in mortality figures in infants in India is probably more apparent than real. From an extensive examination carried out over the last four years, Dr. Ukil is of opinion that the extent of tubercularization of the population in India to-day is midway between that of the African races and the highly industrialized and urbanized European races, and that India and China are probably on the same level. Dr. Ukil has found no bacilli of the bovine type in either glandular or osteo-articular lesions. The reactions of various classes of individuals in India to infection have been carefully studied. In rural areas, predominantly, exudative lesions are found, while the urban populations usually show a more productive type of lesion. The rôle that allergy and immunity play in phthisis amongst Indians is the subject of present investigation. The possibility of application of inoculation with B. C. G. bacillus is being studied. Dr. Ukil is attached to the Medical College Hospital where there is a large outdoor department devoted to tuberculosis. He is also in close touch with the Tuberculosis Association. He is therefore in a very favourable position for the investigation and study of tuberculosis in India.

The researches in kala-azar and in leprosy are also accommodated in the Institute but they are under the Director of the School of Tropical Medicine. An important investigation into the presence of *A. ludlowi* in the vicinity of Calcutta which is being carried out by the Public Health Department of Bengal is also housed in the Institute. This mosquito which normally breeds in brackish water was known to exist in the Southern Sunderban areas of Bengal. In 1931 however a severe outbreak of malaria about 20 miles from Calcutta was found to be due to its presence. An investigation by the Bengal Public Health Department was instituted and it was found that *ludlowi* had taken on migrating habits and was being carried by country boats to the neighbourhood of Calcutta. The enquiry is undertaking preventive measures as well and when complete it will form a most interesting chapter in malarial biology.

LIVER EXTRACT IN EPIDEMIC DROPSY: A SUGGESTION

To the Editor, THE INDIAN MEDICAL GAZETTE

Sir,—Epidemic dropsy has recently been fairly prevalent in Calcutta and I have treated a considerable number of cases. Some of these cases have less oedema than others, and it is generally amongst the former that the heart dilates, and suddenly there is acute cardiac distress with dyspnoea and cyanosis that nothing can relieve, and the cases end fatally.

One of my cases, Mrs. M., was sent to Deoghar for a change where she went for a walk uphill and leucematemesis suddenly started. She came back to Calcutta and had several bouts of hæmatemesis with at the same time a peculiar mottled dark hue in the face and tenderness over the hepatic region. She had looseness of the bowels also. From the fact that there is undoubtedly a metabolic upset in epidemic dropsy and probably calcium deficiency, from the fact that liver extract is recommended in certain hæmorrhagic conditions, and from the tenderness of liver in the patient the idea occurred to me that liver extract injections might possibly be useful. I gave her one injection and the effect was remarkable. With one injection the hæmatemesis stopped but reappeared a few days later. I continued the injections and her distress gradually subsided. I gave her twelve injections altogether, with ordinary dietetic restrictions, and she has no more symptoms of epidemic dropsy.

Encouraged by the result I have given liver extract injections in more than a dozen cases, irrespective of the symptoms, and have found substantial benefit in all of them. I have used several brands of liver extract. With Hepatopson I found some people became giddy immediately after the injection, but with Campolon and liver extract (Bengal Immunity) I did not find this. A full dose of Campolon seems to be too much for these cases, so I generally give one-quarter to half of the dose. The Bengal Immunity liver extract being less concentrated, I give a full dose.

I am now following the routine practice of giving liver extract and colloidal calcium injections with vitamin D ostelin on alternate days and find the results much better. When the symptoms totally disappear I stop the injections and advise my patients to take liver extract and calcium preparations orally. Although this method of treatment is admittedly empirical and I cannot produce any data, I think it worth while recording my experience as a suggestion to others who might try it and corroborate or contradict my results.

In my opinion there is no doubt that the dilatation of the heart and the tachycardia is remarkably influenced. If the pulse rate is 120 or over, it comes down to about 90 after three or four liver extract injections. Of course it is needless to add that such precautions as abolition of rice diet, absolute rest in bed, and plenty of fresh vegetables and fruits rich in vitamin are essential whatever line of treatment is adopted.

Yours, etc.,

PASUPATI BHATTACHARYYA, D.T.M.

CLINICAL EVIDENCE OF RHEUMATIC FEVER IN THE PUNJAB

To the Editor, THE INDIAN MEDICAL GAZETTE

Sir,—As Dr. K. L. Wig remarks in his contribution to your May issue 'the existence of rheumatic fever in the tropics has always been a disputed point'.

Since coming to Madras eight months ago, I have seen over fifty cases of what is clinically rheumatic carditis.

Wassermann-negative cases of mitral stenosis with or without auricular fibrillation are easily obtained from the outpatient department, as required, for teaching purposes.

Typical chorea in children, though not common, is certainly found here and the occurrence of textbook examples of rheumatic nodules is by no means rare.

Four out of ten children's beds in my medical unit are at the present time occupied by sufferers from acute rheumatism with severe carditis—two males aged 10 and 6 and two females aged 10.

Like other workers in India I have to deplore the unwillingness of relatives to allow post-mortem examinations but there is no apparent reason to doubt the correctness of the clinical diagnosis.

All my colleagues on the medical side of this hospital and a large number of general practitioners here tell me that they have for many years been well aware of the occurrence of acute rheumatism in Madras, which has a typical 'tropical' climate—warm and humid all the year round.

Yours, etc.,

GEORGE R. McROBERT, M.D., F.R.C.P.

CONSERVATIVE SURGERY IN MALIGNANT DISEASE

To the Editor, THE INDIAN MEDICAL GAZETTE

DEAR SIR,—I feel a brief answer is called for by Dr. G. Galstaun's letter of 19th April, 1935, in your May 1935 number, in which he criticizes, quite justifiably, my article on conservative surgery for malignant disease which appeared in the March number of the *Indian Medical Gazette*. He apparently thinks that I consider the comparatively small kilovoltage of the x-ray apparatus installed in the Mission Hospital in which I work as being sufficient for deep x-ray therapy. Nothing is, or was, further from my thoughts; but I wrote the article in question with a very definite purpose—namely to show that even with a very moderate-sized x-ray equipment sarcomas in the limbs can be dealt with by its use, combined with surgery and radium, in such a way as to avoid amputation, and at the same time not be followed by recurrence. As a matter of fact, two of the cases reported by me have recurred; one was in the abdomen, and the small voltage of the x-ray apparatus no doubt determined the recurrence. The other was in the arm, and has since had a fore-quarter amputation. But, as everyone knows, in India patients are very prone to run away directly amputation of a limb is suggested; and any method of dealing conservatively with a disease, for which amputation was formerly considered to be the only treatment, may ensure at any rate that the patient in question does not run away to quacks and certain death.

Dr. Galstaun asks about the dosage of radium in the needles I use; the answer is, as quoted by him, 1 milligram per $1\frac{1}{2}$ cm. of needle. The filtration is 0.8 mm. of platinum. I quite agree with Dr. Galstaun that the ideal treatment of most of the cases I mentioned may have been deep x-ray only, at 200 kilovoltage, but there are large areas in India where there is no x-ray plant of this output within several hundreds of miles; and the primary aim of my article was to show that such cases need not be despaired of, nor amputated, but can be treated with a good prospect of success provided great care is taken at every stage of the process. Regarding figure 5, the section showed a small round-celled sarcoma.

Finally, does Dr. Galstaun really think I am such a fool as to consider that my methods are the 'last word' in the treatment of malignant disease?

Yours, etc.,

T. H. SOMERVELL, M.A., M.B., B.Ch.,

INTRAMUSCULAR VERSUS INTRAVENOUS QUININE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Dr. Soni's letter in your issue of May 1935, page 298, induced me to read once over again my letter and your comments thereon. I find that two very important points seem to have missed both of you, viz, (1) My observations relate only to malaria in Kenya and particularly Nairobi. What holds good here may not hold good elsewhere. (2) Ninety-five per cent of the cases here are subtertian in origin. (Malaria is a notifiable disease here and blood examination is done free of charge.) The gastro-intestinal tract is usually very irritable and it is only in a small percentage of cases that oral administration is a possibility. As a matter of fact even after the cessation of pyrexia vomiting persists in some cases and requires parenteral administration of quinine to control it.

But, apart from the availability of the oral route, I do state that oral administration of quinine is not successful in a majority of cases where that route is possible. I do hold that 85 per cent of the cases here do need parenteral administration at the beginning of treatment at least. After my writing to you there has been an epidemic of malaria here and I have to state that my experience during the same warrants no change in my views.

Dr. Soni raises the question of relapse; it is hard to answer this. In the heart of this otherwise very beautiful town runs a big swamp which is the hotbed of mosquito breeding and which according to official figures is responsible for 70 to 75 per cent cases.

In the immediate proximity and on all sides of the swamp are residential areas. Under the circumstances distinction of relapse from reinfection becomes a problem. I would, however, like to add that I have not gathered the impression that relapses are particularly more marked in cases treated by intramuscular quinine. I should make it plain that I do not regard one injection of quinine as complete treatment and permanent cure. Quinine in some form or other has to be continued if relapses are to be prevented.

Coming to the intravenous route I regret I cannot help disappointing Dr. Soni. I cannot persuade myself to use that route, as the intramuscular continues to be successful in my hands. Any intravenous therapy is more risky than intramuscular and it is not fair to the patient to expose one's patient to unnecessary risk, however slight it may be.

Yours, etc.,

K. V. ADALJA, M.B., B.S.

REATA ROAD,
NAIROBI
(KENYA COLONY),
13th June, 1935.

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have read with great interest the article regarding intramuscular quinine by Dr. Adalja published in the January issue of the *Gazette*.

My contention is that quinine by mouth should be the method of choice; of course one should see that it is retained. For cases where quinine cannot be given by the mouth owing to excessive vomiting or in cerebral

malaria, it should be given intravenously. It is not as dangerous as practitioners think, if the injection is given as it should be given, viz, 5 grains in 5 c.cm. or 10 grains in 10 c.cm. of a 20 per cent glucosed saline, together with three drops of adrenaline at a rate of one minute for one c.cm.

The patient should be watched carefully for any signs of cyanosis or sweating due to fall of blood pressure during the process of injection. The patient should not be allowed to sit up for at least one hour after the injection. A hot drink should always follow the injection.

I had the opportunity of giving any number of these injections in a military hospital. I never observed any untoward result. In only one case was there a fall of blood pressure with signs of collapse, but an injection of adrenaline revived the patient.

As has been pointed out by Chopra, Roy and Das Gupta (*J. M. G.*, LXIX, 560) the average maximum concentration of quinine in the blood is almost the same by both the intramuscular and the intravenous routes; so in cases where injections become indispensably necessary to save or to relieve the patient, I would prefer the intravenous one because of its (1) painlessness, (2) less likelihood to cause tissue injury (blood vessels, nerves, muscles, etc.), and (3) certainty of absorption and utilization in the organism in all cases without a single exception when compared with intramuscular injections.

I had to resort to many intramuscular injections of quinine amongst the inmates of a mental hospital, as there are many who will not take anything by the mouth. But subsequently I tried quinine solutions with rice *conji* by nasal feeding with better results. This was given with the usual feed. Mental patients are so dirty and will not keep their clothes on so that infection occurs through the site of injection and abscesses are formed.

Setting aside the question of mental patients I can recall several cases of abscess formation after intramuscular injection of quinine in well-equipped and well-staffed hospitals, but I do not remember to have ever seen or heard of a single case of abscess formation or phlebitis after intravenous injections of quinine. It must be remembered that parenteral routes should be reserved for emergencies only.

Yours, etc.,

PRAFULLA KUMAR SEN GUPTA, L.M.P.

OUTPATIENT DEPARTMENT,

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL E. W. C. BRADFIELD, C.I.E., O.B.E., V.H.S., Assistant Director of Medical Services, Peshawar District, is appointed to officiate as Surgeon-General with the Government of Bombay, with effect from the afternoon of the 25th June, 1935, *vice* Major-General H. R. Nutt, granted leave preparatory to retirement.

To be Officiating Deputy Director, Medical Services, Northern Command

Colonel A. W. M. Harvey, K.H.S., *vice* Major-General T. G. F. Paterson, D.S.O., K.H.P., on leave pending retirement. Dated 24th March, 1935.

Lieutenant-Colonel J. B. Hanafin, C.I.E., is appointed to officiate as Civil Administrative Medical Officer and Port Health Officer, Aden, *vice* Lieutenant-Colonel E. S. Phipson, C.I.E., D.S.O., granted leave.

The services of Major R. C. Wats, an officer of the Medical Research Department, are placed temporarily

at the disposal of the Government of Bombay, for appointment as Officiating Assistant Director, Haffkine Institute, Bombay, with effect from the date on which he assumes charge of his duties.

The following officers are appointed to the Medical Research Department on probation for two years, and are placed on foreign service under the Indian Research Fund Association, with effect from the dates on which they assume charge of their respective duties:—

1. Major W. D. B. Read.

2. Captain M. Jafar.

3. Captain J. R. Dogra.

The services of Captain P. Shannon are placed temporarily at the disposal of the Government of the United Provinces, with effect from the 4th May, 1935.

The services of Captain C. F. J. Cropper are placed temporarily at the disposal of the Government of Burma, with effect from the 19th June, 1935.

The appointment of Lieutenant (now Captain) Thomas Kyran White is confirmed, 5th February, 1934, with seniority 5th February, 1933, with precedence next below Captain J. Edis-Myers.

The seniority of the undermentioned Lieutenants (on probation) is antedated to the 23rd April, 1934:—

James Duffy.

Kenneth Cunningham.

LEAVE

Lieutenant-Colonel E. S. Phipson, C.I.E., D.S.O., Civil Administrative Medical Officer and Port Health Officer, Aden, is granted leave for 6 months and 21 days out of India, with effect from the 15th April, 1935.

Major J. J. Rooney, an Agency Surgeon, is granted leave for 4 months, with effect from the forenoon of the 18th June, 1935.

PROMOTIONS

Majors to be Lieutenant-Colonels

E. Cotter. Dated 8th June, 1935.

J. M. Shah, M.B.E. Dated 17th June, 1935.

Captains to be Majors (provisional)

Brevet-Major M. S. Gupta. Dated 2nd May, 1935.

S. P. Joshi. Dated 25th May, 1935.

R. Linton. Dated 29th May, 1935.

H. W. Mulligan. Dated 29th May, 1935.

E. G. Hurd-Wood. Dated 30th May, 1935.

A. Tait. Dated 22nd June, 1935.

Lieutenants to be Captains

J. Edis-Myers. Dated 6th October, 1934, with seniority 1st May, 1934.

T. K. White. Dated 5th October, 1934, with seniority 1st May, 1934.

R. de Soldenhoff. Dated 10th October, 1934, with seniority 1st May, 1934.

C. J. Hassett. Dated 6th October, 1934, with seniority 1st May, 1934.

R. R. Prosser. Dated 8th October, 1934, with seniority 1st May, 1934.

E. Parry. Dated 5th October, 1934, with seniority 1st May, 1934.

W. G. Kennedy. Dated 6th October, 1934, with seniority 1st May, 1934.

P. I. Franks. Dated 7th December, 1934, with seniority 1st May, 1934.

B. F. B. Russell. Dated 10th January, 1935, with seniority 1st August, 1934.

Note.—Army Department previous notifications are cancelled in so far as they relate to the above officers.

Lieutenants (on probation) to be Captains (on probation)

J. Brebner. Dated 16th February, 1935, with seniority 1st August, 1934.

W. J. Virgin. Dated 17th February, 1935, with seniority 1st August, 1934.

H. W. G. Staunton. Dated 17th February, 1935, with seniority 1st August, 1934.

J. D. Gray. Dated 17th February, 1935, with seniority 15th August, 1934.

D. W. Taylor. Dated 10th March, 1935, with seniority 22nd October, 1934.

P. H. Addison. Dated 10th March, 1935, with seniority 22nd October, 1934.

C. B. Miller. Dated 17th February, 1935, with seniority 13th February, 1935.

Note.—Army Department previous notification is hereby cancelled in so far as it relates to the promotion of the above officers.

RETIREMENTS

Lieutenant-Colonel R. H. Lee retires 19th May, 1935.

Lieutenant-Colonel W. J. Simpson retires 27th May, 1935.

Relinquishment of temporary commission

Captain K. C. Virmani. Dated 12th June, 1935.

OBITUARY

It is with very great regret that we announce the death in London on 26th August of Lieut.-Colonel H. W. Acton, C.I.C., I.M.S., formerly the Director of the Calcutta School of Tropical Medicine.

After a period of nearly five years without leave Colonel Acton went home on 6th April, 1933; shortly after his arrival in England he became seriously ill, but recovered sufficiently for hopes of his return to Calcutta to be entertained. However, towards the end of 1934, he decided to retire, and his retirement took effect, we understand, from some date in August, a few days before his death.

The news of his death came as a very great shock to his personal friends, especially to those of us who had seen him in London only a few weeks ago looking the picture of health. His death has left us with a feeling of irreparable personal loss, and we extend our sympathies to Mrs. Acton, to his mother and to his two sons.

Notes

ERGOMETRINE

THE isolation of the new ergot alkaloid, Ergometrine, recently described by Dudley and Moir was followed by the commercial issue of the drug by Burroughs Wellcome and Company, London (England), within the short space of three weeks from the first announcement of the discovery (*British Medical Journal*, 6th April, 1935).

The following preparations of the alkaloid are issued for therapeutic use:—

'Tabloid' Ergometrine, 0.5 mgm., for oral administration.

'Wellcome' Solution of Ergometrine, 0.5 mgm. in 2.5 c.cm., for oral administration.

'Tabloid' Hypodermic Ergometrine, 0.25 mgm., for intramuscular injection.

'Hypoloid' Ergometrine, 0.25 mgm. in 1 c.cm., for intramuscular injection.

'Tabloid' Hypodermic Ergometrine, 0.05 mgm., for intravenous administration.

'Hypoloid' Ergometrine, 0.05 mgm. in 1 c.cm., for intravenous administration.

The alkaloid used in these preparations is of a high degree of purity and crystallizes readily from a number

of solvents as described in Dr. Dudley's later communication (*British Medical Journal*, 13th April). Ergometrine is characterized by the rapidity with which it causes contraction of the uterus and is used clinically for this effect during the puerperium.

Given orally, in a dose of 0.5 mgm. to 1 mgm., Ergometrine produces contraction after an interval of 6½ to 8 minutes, the contractions being identical in mode of onset and general character with those produced by active liquid extracts of ergot. It may also be given by intramuscular injection, in a dose of 0.25 mgm. to 0.5 mgm., which produces strong uterine action in 3½ to 4½ minutes. Intravenously, in a dose of 0.05 mgm., a strong response follows in 110 seconds and in a dose of 0.1 mgm. in 65 seconds.

Ergometrine has a pronounced and more rapid action in a dosage smaller than that required in the case of ergotoxine. It is remarkably free from side effects.

Ergometrine is of particular value for routine oral administration after parturition. Ergometrine, for its immediate action followed by ergotoxine ethanesulphonate for its prolonged effect, would appear to be ideal for use during the puerperium.

'WELLCOME' BRAND INSULIN

BURROUGHS WELLCOME AND COMPANY announce that all 'Wellcome' brand insulin is now made with pure crystalline insulin, the insulin of 100 per cent purity. 'Wellcome' brand insulin is, we are told, the first commercial product to be prepared with pure crystalline insulin.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

RINGWORM OF THE SCALP IN INDIA

By N. C. DEY, L.M.P., L.T.M.

and

P. A. MAPLESTONE, D.S.O., M.B., CH.B., D.T.M.

(From the Medical Mycology Enquiry, School of Tropical Medicine, Calcutta, financed by the Indian Research Fund Association)

OUT of 53 consecutive cases of tinea of the scalp that have been seen at the Calcutta School of Tropical Medicine during the last three years 20 have been found to be caused by *Trichophyton violaceum*; the remainder were caused by *Microsporon audouini* with the exception of two cases of favus.

These 20 cases of *T. violaceum* infection included five Europeans, twelve Mohammedans and three Marwaris. No case was over twelve years of age and seventeen were less than ten years old. Six of the cases were found simultaneously in one family. We have not so far discovered any other species of trichophyton as a cause of this form of ringworm in Calcutta, a similar observation being that of Nicolau (1909) in Rumania.

In nine cases there was secondary infection of the skin as a direct spread from the scalp to the neck, and in one case (figure 1) the infection spread over the whole body, but from the histories of all our cases the scalp was always the primary site. In no case did we find evidence of infection of the beard and the nails.

In early cases there is a bald patch with the hair broken off at the mouth of the follicle and level with the skin, giving the typical 'black dot' appearance. From the primary site the infection gradually spreads so that in older cases there are many small areas of baldness which finally coalesce producing large patches. Attempts to remove broken hairs with forceps generally end in failure, for the infected hair is extremely brittle and will not withstand sufficient strain to allow of the root being pulled out.

The majority of our cases showed no signs of active inflammation and pustule formation in the follicles which is described as common by the Italians Truffi, Della Favera (1909) and others. Ramognini (Pollacci and Nannizzi, 1922) recorded 84 inflammatory cases out of a total of 246 cases of 'herpes tonsurans' caused by *T. violaceum*. We found inflammation and pustules in seven. The examination of material from these pustules proved negative for bacterial organisms in every case and we always obtained a pure culture of *T. violaceum* (plate XII, figure 1). This suggests that the so-called 'pus' formation in this disease is caused by the fungus itself.

Castellani (1919 and 1934) described a clinical type caused by *T. violaceum* which he named *Tinea decalvans perstans* and which showed pityriasis scaliness and permanent baldness. A few of our cases showed small permanent bald patches but we found no evidence of scaliness in any of them.

In the nine cases in which the glabrous skin was affected the infection spread from the scalp on to the neck, face and behind the ears. In a certain number we also found patches on the arms and forearms. In one case the infection had become generalized all over the body and limbs (figure 1). For the most part the limbs were affected on the extensor surfaces but on

Fig. 1.—Case showing secondary infection of body. (The lesions were similar on the chest and abdomen.)

the trunk the infection had spread downwards from the scalp both anteriorly and posteriorly so that the back and chest were extensively involved and the case resembled a severe tinea cruris infection.

In a few instances we found superficial desquamating areas which resembled tinea circinata except that there was no vesicle formation, and in none of them could we recover the fungus from scrapings either by direct examination of scales or by cultures. Similar results are recorded by Georgjevic and Miloehevitch (1935).

Diagnosis.—For direct examination of scrapings or hairs we used a solution of equal parts of saturated aqueous solution of sodium sulphide and 90 per cent alcohol, to which distilled water is slowly added until the initial turbidity

disappears. This reagent will not keep for more than two months.

A hair or scale is placed on a slide under a cover slip and a little of the solution is run in from the side. As a rule the specimen becomes clear in less than five minutes; if clearing is delayed, however, it may be hastened by warming the slide. With practice and in the case of good specimens a 2/3 objective with a $\times 10$ Zeiss ocular is sufficient to distinguish the fungus, but diagnosis should be confirmed with a 1/6 inch objective. In all our cases infected hairs showed large spores 3 to 5 μ or more in diameter. In early stages mycelia with septa at long intervals lying along the hair are seen, and as the fungus becomes older arthrospores form and the septate divisions of the mycelia become shorter. The spores are distributed axially along the hair and give it a characteristic beaded appearance which, apart from the difference in size of the spores, is readily distinguished from the mosaic appearance of the small-spored infection by *Microsporon audouini* (figures 2a and 2b). Epidermal scales show septate mycelia

Fig. 2a.—Infected hair. High power $\times 450$.

Fig. 2b.—Infected hair. Low power $\times 80$.

which cannot be distinguished from other types of ringworm fungi by direct examination so that cultural methods have to be resorted to to establish the diagnosis.

Culture.—In addition to obtaining growth from infected hair or scales of epidermis we have had success by inoculating 'pus' from infected follicles on the scalp (plate XII, figure 1). Although this fungus grows fairly well on ordinary laboratory media we got the best results with Sabouraud's maltose-peptone agar and Pollacci media. On the so-called natural media of Langeron and Milochévitch (1930), i.e., cereals, etc., growth seldom occurred.

Characters of growth.—On Sabouraud's medium there appeared in about three to four weeks a smooth faviform growth about 2 cm. in diameter, raised above the surface of the medium and showing a varying degree of violet coloration (plate XII, figure 2). The growth was always found to contain a considerable amount of moisture which became evident when it was cut up for subculture or for purposes of examination.

The above is the type of growth that we designate as typical although variant forms such as we describe below were perhaps more often obtained.

(1) **Colour variation.**—The typical violet colour gradually fades with each subculture until the growth is finally cream coloured (plate XII, figure 3) although sometimes the primary culture may be cream coloured (plate XII, figure 3a). Sometimes subcultures are patchy being violet in one part and pale in another. It was also noted that cultures from 'pus' often showed some colonies typically violet whereas others were white or cream (plate XII, figures 4 and 5). We have been unable to maintain in subcultures the same depth of tint as that of the original although those made on glucose agar and Pollacci medium did not lose their colour as rapidly as those grown on other media. Catanei (1931) considered that violet and cream cultures of *T. violaceum* were distinct species because he held that they retained their characteristic colour after animal passage but we have obtained on more than one occasion mixed violet and cream colonies from a single inoculum (plate XII, figures 4 and 5), therefore using colour as a specific character does not appear to be sound. This is further borne out by the finding that the violet colour always fades and finally disappears on repeated subculture. Another difference we noted was that in a medium composed of

Water	1,000	c.c.m.
Agar	15	grms.
Sucrose	30	"
Sodium nitrate	2	"
Dipotassium phosphate	1	gm.
Magnesium sulphate	0.5	"
Potassium chloride	0.5	"

we always found a pink colour instead of violet in primary cultures, but on subculture this also disappears. Although we tried to produce other colour variations by using different media in the way that Acton and McGuire (1927) did in

1

3

4

5

6

2

3 A.

the case of *Epidermophyton cruris* we were unable to do so.

(2) *Character variation*.—The primary culture may be flat on the surface of the medium, of a very light violet tint, and perhaps raised a little in the centre with no radiating furrows. Subcultures from such a growth were also of the same type.

Ducrey and Reale (1896) first drew attention to the tendency of this fungus to undergo pleomorphic changes. This is most often observed in old subcultures showing short white duvet, but occasionally we got the same appearance in primary cultures after a lapse of six weeks or longer (plate XII, figure 6). Subcultures from these altered growths are usually of the same type but at times a modified typical growth is obtained. Microscopically the mycelia are thin and long and have spore-like structures within them. In well-slide preparations both terminal and intercalary chlamydospores are found, and old mycelia show arthrospores. The terminal chlamydospores may be oval or round; they measure 16 to 18 μ in diameter and when old show a double-wall formation. The arthrospores are usually irregular with unilateral swellings; other arthrospores without any swelling of the mycelia also occur; in this case the mycelia show close-septate divisions producing short sections with square-cut ends which in time may become more oval or rounded.

Animal inoculation.—The skin was shaved and an emulsion of an active culture was rubbed on the spot with a glass rod. We inoculated one rabbit, one guinea-pig, one white rat and two monkeys. The guinea-pig and the rat were entirely negative, the rabbit had a slight patch of erythema with a little scaling which cleared up spontaneously, and the first monkey got infection of the hair. Cultures made from this animal showed a more reddish tint than the original culture. In the second monkey a culture of *T. violaceum* which had lost the violet

the infection had spread beyond the area originally inoculated (1½ inches in diameter). On microscopic examination the hair showed an endo-ectothrix infection (figure 4) and culture

Fig. 4.—Infected hair from favic lesion of monkey (magnification $\times 320$).

Fig. 3.—Favic lesion produced in monkey

colour on subculture was rubbed on a shaved area on the back. Infection took place in 10 days and developed further to a typical favic lesion (figure 3). In one month and eleven days

gave a cream-coloured growth of *T. violaceum* on Sabouraud's maltose-peptone agar.

Classification.—The generic name *Trichophyton* was originally used to include fungi which were considered to infect the hair only and did not spread on to the skin, but this distinction is no longer valid for, although the ringworm fungi all show certain preferences for either hair or epidermis, practically all of them have now been found to be capable of growing in both these structures; it is accordingly proposed to consider classification on a botanical basis, which is much more satisfactory than the clinical. If considered on the cultural appearances in Sabouraud's medium *T. violaceum* is seen to be really an *Achorion*, for on this medium it produces a faviform growth unlike the downy cultures of *Trichophyton*. Microscopic examination shows arthrospores, intercalary and terminal chlamydospores similar to those found in *A. schonleini*. Further support to this view is lent by the typical favic lesions we produced in one of our monkeys, and Georgjevic and Milochevitch (1935) record a case in a human being with favic scutula caused by *Trichophyton album*. Accordingly we consider *T. violaceum*

is more correctly classed as an *Achorion*, and we have also produced proof that violet or white colour is only a variation, so the name of this fungus with its synonymy is as follows:—

Achorion violaceum (Bodin, 1902).

Synonyms.—*Trichophyton violaceum* Bodin, 1902.

Trichophyton album Sabouraud, 1909.

Ectotrichophyton album Castellani and Chalmers, 1918.

Trichophyton glabrum Sabouraud, 1909.

Trichophyton (indicum) violaceum was identified as a variety by Acton and McGuire (1929) because it primarily infects the hair follicles on the limbs only rarely spreading on to the scalp, and cultures habitually show a much deeper violet than the ordinary species.

T. (decalvans) violaceum was distinguished by Castellani (1919) because of slight differences in the clinical appearance of the scalp infection from the usual type, but the cultural characters were practically identical with those of *T. violaceum*, therefore this is probably also a synonym of *A. violaceum*.

Summary

(1) The existence of *Trichophyton violaceum* (Bodin) is recorded for the first time in India.

(2) No other species of *Trichophyton* has been found during the course of this investigation.

(3) The cultural characteristics of this fungus have been described.

(4) It is suggested that on botanical as opposed to clinical characters this fungus would be more correctly classed in the genus *Achorion*.

SOME OBSERVATIONS ON DERMAL LEISHMANIASIS

By R. O. A. SMITH, D.T.M., I.M.D.
and

K. C. HALDER, L.M.F.

(From the Kala-Azar Enquiry under the Indian Research Fund Association, School of Tropical Medicine, Calcutta)

SINCE Brahmachari described the first case in 1922 of this sequel of kala-azar, the number of cases presenting themselves for diagnosis and treatment has steadily increased. At the School of Tropical Medicine we now meet with an average of about 60 cases each year. A certain number of cases attend for treatment at other clinics and by private practitioners, but that a large number do not trouble to seek advice regarding their condition is made evident by the fact that many patients are noticed in the streets who do not seem to realize that anything is amiss with them—or, if they do, they do not attach any importance to the condition, especially in the early stages, when the disfigurement is not marked.

The early lesions cause no inconvenience to the patient whatever and it is only when the condition advances to the nodular stage, and there is a suspicion that the condition is leprotic or syphilitic, that many patients come for advice and for treatment. This is true of patients from the mofussil, the majority of whom present themselves with advanced forms of the disease, than of those from Calcutta itself, where the advantages of the skin clinic at the School of Tropical Medicine are made full use of; many early cases are seen in this clinic. The greater number of cases seen by us have been referred to us by the officers in charge of the leprosy and skin departments. This opportunity is taken of acknowledging their kind assistance.

A few cases are seen amongst patients treated for kala-azar at the outpatient department who present themselves for treatment for some febrile ailment which they think is a return of kala-azar, and they are not aware that they have skin lesions.

- Fig. 6.—Duvet formation in primary culture after a period of six weeks' growth.

Sandflies, *Phlebotomus argentipes*, are as easily infected by feeding on these dermal lesions as by feeding on cases of kala-azar and the fact that the organisms are identical renders this condition a very important one epidemiologically. Although the experiments to transmit *Leishmania donovani* to human volunteers by the 'bites' of infected sandflies, *P. argentipes*, have so far proved negative, the bulk of the evidence accumulated against these midges, and the fact that on four occasions at least *L. donovani* has been transmitted to hamsters by the 'bites' of infected sandflies, point very strongly to these midges as the natural vectors of *L. donovani* in man. The reasons why a larger percentage of experimental animals has not been successfully infected and also the failure in man have yet to be discovered.

The fact that dermal cases serve as a reservoir of *L. donovani* over long periods, and possibly all their lives if no treatment is taken for the cure of the condition, renders them a greater source of danger to their neighbours than cases of the visceral disease—where the patient either recovers under proper treatment, or if untreated most often dies in a definite space of time.

P. argentipes are most easily infected by feeding on the nodular lesions, but they can be infected fairly readily by feeding on the depigmented patches as well, and indeed the feeding of sandflies on such patches is a more certain means of diagnosis—if a definite diagnosis is needed—than either smear or culture from the part in question. By enclosing sandflies in a specially-made cage with 'holting' cloth these midges can be made to feed on any particular part of the body as required and a definite diagnosis made.

Mention may here be made of a class of nodular lesions where the cellular reaction seems to be far in excess of the parasitic infection and such nodules do not always show leishmania in smears when taken in the usual way. We have seen three cases of this nature—in one a diagnosis was made by feeding sandflies on the lesions; in the second by culture; the third was diagnosed clinically on the good response to the antimony treatment given.

That a certain number of cases act as carriers without showing any lesions in the skin is borne out by the fact that in one case at least, out of five where the experiment was done, infected flies have been obtained by feeding on the chin of a man who showed no obvious lesions, but who had had kala-azar two years previously. The sandflies were fed on the area round the chin and mouth for the reason that signs of dermal leishmaniasis often appear first on these sites and also because it was noted that the area round the waist, which is fairly constantly under pressure in Indians who wear 'dhotis', is very often not affected by dermal lesions, even when practically the whole of the trunk and

limbs are depigmented (figure 1). It was difficult to explain this feature except by the reason of the pressure which is applied fairly constantly both day and night over this area.

Use was made of this observation to test the value of a pressure bandage on an infected limb but though a certain amount of difference in pigmentation was noted in parts where the bandage was fairly firmly applied the results were not encouraging from a therapeutic aspect.

We have nothing to add to our present knowledge regarding the distribution of the lesions, the age, sex and caste of the patients presenting themselves for treatment. Our figures compare very closely with those reported

Fig. 1.

by Napier and Das Gupta (1930 and 1934) in their clinical studies of the disease.

We have had one case where the dermal and visceral lesions were present at the same time. The child in question had had two courses of one of the pentavalent compounds of antimony by private practitioners and when first seen was found to be very anæmic with a blood picture suggestive of pernicious anæmia. A blood culture and aldehyde test were done at the same time. The aldehyde test was weakly positive—but the blood culture showed many flagellate forms on the 12th day. The spleen was enlarged and so was the liver; the temperature was irregular. This case showed a certain intolerance to antimony—the first injection causing severe hepatic pain, a rise in temperature after 24 hours, and inflammation of the lips and

tongue. Treatment by grey powders internally, belladonna plaster over the liver and the injection of neostibosan every 4th day caused a complete cure of the visceral condition. A good improvement of the dermal condition was also found when the patient reported three months later.

We would, however, like to draw attention to certain types of the disease which we have seen in the past two years. Napier and Das Gupta (1934) have described seven clinical types of this disease. We would like to add a new one to this series, viz, a fibroid type. A photograph of such a case is given, figure 2 (a) and (b). Two other types which are really variants of the nodular form are worthy of mention—a leprous type and an ulcerative type.

Fig. 2a—Fibroid type; before treatment

Fig. 2b—After treatment

(i) *Leprous type*.—The nodules in this form of leishmaniasis have often been mistaken for those caused by Hansen's bacillus before a correct diagnosis has been made, but the case whose picture is herewith appended is more like a case of leprosy than any we have yet encountered. He was treated with antimony and iodides, and made an excellent recovery as the picture after treatment shows, figure 3 (a), (b) and (c).

(ii) *Fibroid type*.—This type is not quite the same as the hypertrophic type described by Napier. When first seen, the thickening of the

Fig. 3a—Leprous type

phalanges suggested some form of dactylitis and an x-ray picture was taken to observe the condition of the phalanges; these were found intact and the swelling was confined to the soft structures. The only other lesion shown by this patient was slight erythema of the face, which might very easily have been overlooked, figure 2 (a) and (b).

(iii) *Ulcerative type*.—At least four cases were seen, one of which is depicted in figure 4 (a) where there was definite ulceration of some of the nodules. The parasites, *L. donovan*, were demonstrated from the borders of the ulcers in much the same manner as in *L. tropica* infections.

Figure 5 is also the picture of another case where there was a certain amount of breaking down of the nodular tissue which in this case was limited mainly to the nose. It is unfortunate that the patient who lived out of Calcutta would not stay in hospital or remain here for treatment after a diagnosis was made, so that the ultimate result of the lesion could not be traced.

Fig. 3b.

Fig. 3c.—Same man; after treatment.

Fig. 4a.—Before treatment.

Fig. 4b.—After treatment.

Lesions of the palate and mucous membranes have been mentioned by other writers on this

Fig 5.

Fig 6

subject; we have had one case, depicted in figure 6, of a definite muco-cutaneous ulceration. This patient as the picture shows had an ulcer on the lower lip and also two shallow ulcers of the dorsum of the tongue, one on either side of the middle line. *Leishmania* were demonstrated from the lip lesion but not from that on the tongue—which healed up spontaneously in a few days after admission to hospital, before any treatment other than iodides was given.

Treatment.—While antimony is indispensable in the treatment of this condition, we would like to mention the efficacy of potassium iodide as an adjunct to the treatment with the pentavalent compounds of antimony. The effect of a course of iodides before a course of antimony is most apparent in certain forms of nodular dermal leishmaniasis—particularly the leprous, xanthoma and fibroid types. The results in these cases are fairly rapid, the unsightly nodules clearing up rapidly in a few weeks. One case treated in the hospital showed very rapid improvement; in this case the effect of the iodides was to cause ulceration of the nodules in four places, and as soon as antimony was begun the lesions were seen to shrink from day to day.

The effect of potassium iodide is less marked in those cases with isolated nodules and in purely depigmented cases, but even in such cases our results have led us to believe that the lesions clear up quicker when treated with iodides and antimony than with antimony alone. We have tried various local applications on the purely depigmented lesions—such as liniment of iodine, trichloroacetic acid, oil of bouchi, and an ointment of berberine sulphate made up with a special base—with no improvement whatever.

Vaccine.—A vaccine made of flagellates was used in a few cases early in 1933, but the results were not encouraging and this treatment was given up.

The routine adopted was to treat each case with increasing doses of potassium iodide till symptoms of intolerance were noted or there was some change in the nature of the lesions; the iodide was then withheld and a course of antimony begun. A course of antimony consisted of 12 to 15 injections, making a total of 3 to 4 grammes of the drug. A second course of iodides and antimony was then given after a rest of two or three weeks and the patient told to report after a month so that we could observe the condition of his lesions.

It is unfortunate that many cases, mostly with purely depigmented lesions, do not respond readily to treatment as described above, and many of them cease attending before a cure has been effected, but our experience suggests that many of these cases do ultimately get cured if they have had the patience to take a sufficient amount of the drug.

In some instances where there were isolated nodules, we treated the nodules locally with injections of 2 per cent berberine sulphate. These

injections are painful and only one or two nodules could be treated at a time but the results

Fig 7a—Before treatment.

Fig. 7b.—After treatment.

are fairly certain; the nodule shrinks rapidly after the preliminary inflammation due to the

drug. It was suspected before that this local inflammation was also beneficial to the other lesions on the body for, after a few of the nodules have been treated in this way, depigmented lesions have been seen to resolve faster than when the antimony treatment alone was given. Further evidence to support this assumption was obtained in two cases; one of these came to us with ulcerated lesions, in the second the lesions ulcerated after the administration of potassium iodide, and both healed very rapidly after the administration of antimony.

Figures 7 (a) and (b) and 8 (a) and (b) are of cases before and after treatment, the former being a case passed on to us by Dr. L. E. Napier when he relinquished charge of the

Fig. 8a—Before treatment

enquiry, and the latter a case in which the effect of the iodides was to cause ulceration of these nodules preliminary to healing

Acknowledgment

Our thanks are due to Dr. L. R. Sharma for much assistance during his period of work with us and also to Dr. S. Mukerji and Jemadar Chiranji Lal for much practical assistance.

NERVE AND CORD DEGENERATION REFERABLE TO VITAMIN-A DEFICIENCY

By LUCIUS NICHOLLS, M.D., B.C., B.A. (Cantab.)

Bacteriological Institute, Colombo, Ceylon

In 1933 I inspected a large number of prisoners in the jails of Ceylon for signs and symptoms of nutritional deficiencies. The results were reported in this journal (Nicholls, 1933). The conditions which were attributed to vitamin-A deficiency were:—a papular dry skin eruption (phrynoderma), night blindness, dimness of sight, xerophthalmia, keratomalacia, a lowered resistance to dysentery, and neuritis. The last was so common that a diagnosis of neuritis had been made during 1932 in the case of 41 patients admitted to the Colombo Prison Hospital, and 2,397 treated at the dispensary. At that time the diagnosis was accepted, but at a later date more careful clinical investigations

(Continued from previous page)

made this doubtful. There was considerable uniformity in the symptoms in the early stages. The patients complained of a burning sensation of the hands and sometimes of the feet, and numbness, tingling and weakness of the limbs. Many patients had pain when the muscles of the calves were squeezed. The reflex responses varied and were increased, normal or diminished. When the patients were placed on an improved diet recovery soon took place. A few patients developed what appeared to be a more advanced stage of the condition; and in these the clinical signs were so variable as to be bewildering, and when experienced physicians examined these patients they hesitated to make definite diagnoses and offered tentative suggestions such as:—progressive muscular atrophy of unusual distribution, 'neuritis', 'beri-beri', early 'tabes dorsalis' and 'a lesion of the pyramidal tract is suggested'. Most of the patients in the later stages recovered slowly in hospital. Therefore either the prisoners, the majority of whom were young men, were at that time particularly liable to paretic disorders from a variety of causes or one type of cause was producing a variety of paretic signs.

Signs of degeneration of nerve tissue in women in the later stages of pregnancy and during lactation have been recognized for many years in Ceylon as being far from a rare occurrence.

The early symptoms in these cases are similar to those described above for the prisoners, they start with burning sensations in the palms of the hands and sometimes also in the soles of the feet, there is tingling, numbness and muscular weakness of the limbs. Many patients do not have signs other than these, others develop mild degrees of paresis and ataxia. The great majority of the patients recover soon after childbirth. Occasionally the condition becomes worse during lactation and results in much paresis and ataxia. A few of these advanced cases are to be seen in the wards of the General Hospital in Colombo.

I selected two cases in the medical wards in the charge of Dr. P. B. Fernando, and he supplied extensive notes on them and has kindly given me permission to publish these. One case will be sufficient as it is typical of many, though not of all.

Notes on a case of paresis and ataxia of pregnancy

S. H., age 33, wife of a petty trader. Admitted on 7th March, 1935, when she was unable to walk and had loss of power in the arms and legs.

History.—Two and a half months prior to admission her sixth child was born; it was a normal delivery. Two months before the confinement she noticed numbness and tingling of both feet and hands. Gradually the numbness and tingling spread to the arms and legs. The condition became steadily worse after childbirth, and three weeks prior to admission to hospital she was unable to walk or even stand, and she could not work with her hands owing to loss of power and ataxic movements.

PLATE XIII

Fig. 1.

Fig. 3.

Fig. 2.

Fig. 4.

Fig. 5.

There was no history of venereal disease. She had had malaria and continued fever two years ago. Three of her six children have died, two of convulsions and one of typhoid fever.

Diet.—Her usual diet consisted of rice, vegetables, and fish. She took very small quantities of milk (just enough to flavour the tea). She stated that she never took meat, eggs, butter or ghee. For several months prior to the onset of the numbness she had been off food owing to the vomiting of pregnancy and was nearly starving herself. (There was no history pointing to lathyrism; lathyrus peas are not eaten in Ceylon.)

Clinical examination.—The patient appears well developed, there is no wasting, she had fever of 101°F. on admission. Rather anæmic.

Heart.—Limits normal. Harsh murmur over the base. Pulse volume fair.

Lungs.—Nothing abnormal.

Abdomen.—Spleen enlarged, liver enlarged, bowels regular.

Urine.—Specific gravity—1020; albumin and sugar—nil; deposit—pus cells (about 6 to a field) and uric acid crystals.

Fæces.—Ascaris, necator and trichuris ova present.

Blood.—Malarial parasites not found. Wassermann test negative. Erythrocytes 3,760,000 per c.mm. (on 8th April, 1935); reticulocytes 1.5 per cent, average size of red blood corpuscles 7.6 μ , leucocytes 5,800 (58 per cent polymorphonuclears and 42 per cent lymphocytes). Hamoglobin 75 per cent.

Mentality.—The patient is intelligent, she is not emotional and her speech is normal.

Cranial nerves.—All normal. Pupils react to light and accommodation; no nystagmus.

Motor system.—There is no wasting of the muscles. There is marked weakness of the arms and legs. Patient can raise the legs from the bed, but not against light pressure; her finger grip is weak; flexion and extension of the arms against pressure is very weak. Wrist drop and foot drop are present on both sides. The patient cannot stand or walk.

Sensory.—There was impairment of touch and discrimination of heat and cold over the dorsum of the feet and extending up to a little below the knees on the antero-internal aspect of the legs. Pin-pricks could be felt all over the limbs. The joint sense was lost, the patient being unable to state correctly which way the toe was bent. Romberg's sign was present.

Inco-ordination.—There was inco-ordination of movements of both arms, more marked on the left side as shown by the finger to nose test. There were coarse tremors of the hands and forearms as she attempted to use them.

Reflexes.—(a) Superficial:—

- (1) conjunctival, present and equal.
- (2) corneal, " " "
- (3) abdominal, " " "
- (4) plantar, flexor response.

(b) Deep:—

- (1) knee, absent.
- (2) ankle, "
- (3) biceps, "
- (4) triceps, "

Sphincter action was normal.

Cerebro-spinal fluid.—This was clear and was not under tension. Cells were not increased, sugar 56 mgm. per cent, chlorides 700 mgm. per cent. Proteins gave Nonne-Apelt—negative and Pandy's—weak positive. Lange's curve 00000012210.

Treatment.—The patient was given cod-liver-oil, and an iron mixture three times daily and marmite daily. Electrical treatment of the muscles was started on 22nd March.

In April the patient was given treatment for hook-worm infection.

Progress.—The condition of the patient slowly improved and on 10th May two months after admission the notes state 'Patient very much improved. Can walk about without assistance, muscle tone good,

inco-ordination and ataxia much less, but still present. Romberg's sign is still present. Superficial sensations—touch (cotton-wool) absent over dorsum of feet, but present over the rest of the legs. Heat and cold sensations have likewise returned over the legs but are still absent over the dorsum of the feet'.

Post-mortem material

The next necessary step was to obtain material for microscopical examination. But it became apparent that many years might elapse before post-mortems could be obtained on an adult, because the mortality rate among these patients is exceedingly low, and post-mortems are not easily obtained in Ceylon.

E. Mellanby (1926 and 1934) has shown that when young dogs were fed on diets deficient in fat-soluble vitamins they develop inco-ordination of movements, and when sections of their cords are stained by Marchi's osmic acid method varying degrees of demyelination of the nerve fibres are revealed.

The death rate among young children of the lower classes in Ceylon is high and malnutrition, marasmus and debility are the causes of death which are returned for many of these.

Signs of vitamin-A deficiency such as keratomalacia and phrynoderma are common in these marasmic children (Nicholls, 1934). A clinical examination for signs and symptoms of nerve degeneration in these children was carried out and found to present great difficulties, because these children are very irritable and any handling produces crying and writhing, and this is increased when the muscles of the calves are gently squeezed, so that there is little doubt that this causes pain; but satisfactory examinations for reflex responses could not be made, even in cases where there was advanced weakness and atrophy of the muscles.

A considerable number of post-mortems have been obtained on young children, and eight of these children had shown signs of vitamin-A deficiency during life.

Pending the permission of the parents for the post-mortem it was necessary to prevent changes in the cords, and therefore 50 c.cm. of 10 per cent formalin in normal saline was injected intrathecally into each child. This was done in the first cases, but later with the assistance of Dr. O. C. Hill (Professor of Anatomy) the whole body of each child was injected through the femoral artery. These procedures were found to preserve the cords in good condition. The assistance of Dr. E. K. Wolff (Professor of Pathology) was obtained for the preparation of many of the sections. Marchi's osmic acid method was used for all the sections.

A post-mortem was made on a child aged 2 years, who had a history and showed signs of malnutrition and had died of a terminal broncho-pneumonia.

A piece of the spinal cord was removed with the posterior and anterior roots attached, sections were cut and stained; figure 1 (plate XIII)

is taken from a section of the posterior nerve roots; it shows a few degenerated nerve fibres especially in the upper right-hand quadrant of the photograph. A section of the cord of this child was searched but markedly degenerated nerve fibres were not found; figure 2 (plate XIII) is from the posterior columns. These serve as a contrast for sections (which were prepared at the same time) of nerve roots and cords, which showed much more advanced nerve fibre degeneration.

A post-mortem examination was done on the body of a child aged 2½; the cause of its death had been returned as marasmus. The body was emaciated, there was phrynodermia of the skin, and early signs of keratomalacia. The heart and lungs showed no signs of disease; the liver, spleen, kidneys and intestines were more or less normal, and the examination did not reveal any definite cause of death. Sections of the posterior nerve roots showed numerous nerve fibres in various stages of degeneration; and sections of the cord showed many degenerated fibres. The degeneration was most marked in the posterior columns but was not confined to them, degenerated fibres were seen to be scattered throughout the lateral and anterior columns. The anterior roots also showed some degenerated fibres. Figures 3 and 4 (plate XIII) are from the posterior roots and the posterior columns, respectively.

The posterior nerve roots and posterior columns of the cords of all children who had shown signs that were attributed to vitamin-A deficiency had degeneration of about the same degree as that shown in plate XIII, figures 2 and 4. And also in all cases the anterior roots and the lateral and anterior columns showed degenerated fibres.

But two children who had not shown during life any definite signs of vitamin-A deficiency, though it does not follow that they were not suffering from this deficiency, had a fair degree of degeneration of the nerve roots and cords. One of these had been diagnosed in life as suffering from malnutrition and had died with a terminal diarrhoea. The other had 'nutritional oedema'; figure 5 (plate XIII) is from a section of the posterior nerve root of the latter.

Discussions.—Mellanby has fairly definitely established the fact that some amount of the fat-soluble vitamins is necessary in the diets of dogs for the health of their nervous systems. The poorest classes of the teeming East live on diets which are definitely deficient in vitamin A, and when greater strains are thrown upon the metabolism as when women are pregnant, prisoners are placed on penal diets, and children are weaned on cereals and a few coarse vegetables, signs and symptoms of degeneration of the nervous system are to be expected among them.

It is seldom that a mean diet is deficient in only one food factor; but in primary aetiological

enquiries it is necessary to dwell largely upon the most salient deficiency and, although it is suggested that vitamin-A deficiency is the cause of the symptoms, signs and microscopical appearances of nerve fibre degeneration described here, it is not suggested that other deficiencies or even neurotoxins may not play a part in some cases.

It is widely accepted that a deficiency of vitamin B₁ is the main aetiological factor in beri-beri; but most observers consider that other factors such as neurotoxins or other dietary defects may have an ancillary or even determinative action. Mellanby (1934) considers that although a deficiency of vitamin B plays an important part in the aetiology of beri-beri yet it is a deficiency of vitamin A which causes the polyneuritis. A point in favour of this is that outbreaks of beri-beri are particularly liable to occur among gangs of labourers and others who cannot afford comestibles of animal origin rich in vitamin A, and they are usually away from access to fresh garden produce. But beri-beri, showing the usually accepted signs and symptoms, is very uncommon in Ceylon, where vitamin-A deficiency is rife.

It may be that beri-beri and such conditions as the paresis and ataxia of pregnancy are closely allied and the signs, symptoms and distribution of the nerve fibre lesions are determined by the relative deficiencies of vitamins A and B₁ (and perhaps others) in the diets; in which case they fall into a natural group characterized by more or less subacute combined degeneration in which complete regeneration may take place.

The lack of uniformity of the symptoms and signs among the prisoners was doubtless due to different nerves and columns of the cords being affected to varying degrees.

LUMBAR SYMPATHECTOMY IN THE TREATMENT OF CIRCULATORY DISEASES

By M. M. CRUICKSHANK

LIEUTENANT-COLONEL, I.M.S.

General Hospital, Madras

TELFORD and STOPFORD (1935) state that 'whilst cases of onychia have showed rapid healing, the outlook for sympathectomy when gangrene is actually present is not good. The operation is hardly worth while, excepting that a sympathectomy may render it possible to amputate at a lower level than the customary above-the-knee operation.

Many of the patients suffer from wellnigh intolerable "rest-pain" which causes a rapid depreciation of their general health. In such cases it is well worth while to consider a sympathectomy even if the vascular condition of the limbs offers but scanty hope of success as regards function. The relief of pain after the sympathectomy is often complete and we have found this one of the most striking and gratifying results of the operation.

I feel that there is, in India, room for a more extensive use of lumbar sympathectomy in the treatment of cases of gangrene in the initial stages of the disease and in those cases where the first evidence of vascular disease is the appearance of an onychia or a trophic ulcer.

To say that vasospasm is but an incident in the disease and that the underlying pathology must negative any permanent benefit, and to leave it at that, is simply to deny to the sufferer the benefit which surgery offers to him.

If however we in India pick out only those cases that show some improvement in circulation, as measured by surface temperature after inoculation with T. A. B. vaccine or after the administration of a spinal anæsthetic, then we shall miss many suitable cases. In India, when and where the room temperature approximates and often exceeds body temperature, Brown's vasomotor index is of little use for the purpose of selecting cases. The temperature of the limb in which vasospasm exists approximates room temperature, and the rises in the mouth and limb temperatures after inoculation with the vaccine will then be approximately the same, though granted that in the case of the affected limb the rise may be delayed.

After spinal anæsthesia the temperature of the feet as recorded by a surface thermometer is said to rise from 5°C. to 8°C., but this does not occur in India where a rise of 1° or 2°C. is all that can be expected.

The following results are typical of what happens, at least during the warmer weather in Madras :

TABLE

Showing temperature in degrees centigrade before and after administration of spinal anæsthetic, 17 c.cm. of novocaine, 1 per cent

	Before	After	Before	After	Before	After
Mouth temperature.	36.6°	36.6°	37°	37°	36.8°	36.8°
Limb temperature.	34°	35°	34°	34°	33°	35°
Ward temperature.	34°	34°	33.5°	33.5°	34°	34°
Age of patient in years.	55		35		30	

The environmental temperature test could of course be made use of with more accurate results.

It is interesting to note that Ito and Asami, who arrived at the idea of treating vasospastic diseases by ganglionectomy, found their patients amongst the field workers of Japan. There, as in South India, the former is subject to long continued exposure standing in water planting rice during the rainy season.

Before the stage when 'trophic' ulceration appears there is a period when, if the patient were seen, he would complain of cold, dull, aching feet, perhaps with some slight degree of cyanosis. These are the cases which can receive great benefit by operation, not those, such as we at present see, that already have suffered for perhaps years with pains in the legs on walking and have lost parts of toes, perhaps several toes, from local spontaneous gangrene, and the treatment of which ends in amputation of the affected limb. The cases where the pulsation in main arteries is still present are those which will do well after a sympathectomy. That even late cases can benefit in some degree from a lumbar sympathectomy is evidenced by the medical histories of three cases operated upon within the last four months.

Case 1.—Male, aged 33 years; admitted with gangrene of the second toe of the right foot.

Two and a half months ago he began to suffer from excruciating pain in the second toe of the right foot, the pain extending up his leg and interfering with sleep. The patient got relief from pain by hanging his leg over the edge of the bed, in which position he now always sleeps.

Local condition.—Right foot cold, cedematous; the second toe is black and the skin on the dorsum has peeled off. The toe is very tender to the touch.

The femoral pulse is felt on both sides but is very feeble.

The popliteal and posterior tibial pulses on the right side are not felt.

Temperatures before and after T. A. B. inoculation

	Before	After
Right thigh 34°C.	37°C.
Right foot 29°C.	34°C.
Mouth 36.4°C.	38.5°C.

Operation.—On 13th February, under open ether, incision made on right side as for exposure of the ureter. The sympathetic chain was readily demonstrated and numbers 1 to 4 lumbar ganglia with the intervening chain resected.

After operation but on the same day the temperatures were:—

Thigh—36°C.
Foot—34°C.

On the 16th February, these were the same.

On the 23rd February, the patient stated that the pain in the leg had gone, but that pain in the gangrenous toe persisted to some extent, and as the toe was separating very slowly it was amputated and the patient discharged on the 16th March, 1935.

The pulse did not return in the posterior tibial artery, but with improvement in collateral circulation relief was very marked. In the region of the gangrenous toe, where degenerative changes had occurred in the vessels, improvement could not be expected.

Case 2.—Male, aged 25 years; admitted to hospital on the 5th March, complaining of pain in the left great toe and of an ulcer, which refused to heal, on the same digit.

The condition commenced five months ago, the pain being severe enough to keep him awake at night. Soon after the onset of pain an ulcer appeared on the dorsum of the great toe. The pain became progressively worse and the ulcer spread to such an extent that the terminal phalanx of the toe had to be removed in the outpatient department on the 3rd March.

Though a Mohanmedan, he gave a history of smoking 5 or 6 cigarettes a day. He denied any addiction to alcohol and there was no history or evidence of venereal disease.

The region of the ulcer was exquisitely tender to the touch; pulsation in both femorals was vigorous, in the popliteals feeble, and in the posterior tibial and dorsalis pedis absent. Urine was normal. Blood sugar 0.083 per cent. Wassermann and Kahn—negative.

Temperatures before and after T. A. B. inoculation

	Before	After
Left foot	32.5°C	36°C.
Mouth	36.4°C.	39.4°C.

Operation.—On the 18th March, under open ether, a kidney incision extending from the angle of the ribs with the erector spinae to one inch in front of the anterior superior spine was made.

The exposure was not so good as with the 'ureter' incision of the first case and the demonstration of the various branches of the sympathetic was not so easily carried out.

After operation, but on the same day, the temperatures were:—

Left foot—32.5°C
Mouth—36.8°C.

On the 20th April, the patient stated that the pain in his left great toe had gone. The ulcer soon began to show signs of healing and, as he was apparently satisfied with the results of the operation, he left the hospital on his own accord.

Case 3.—Male, aged 40 years; admitted to hospital on the 28th May, complaining of the presence of an ulcer on the under surface of his left great toe, which had persisted for over one year.

He gave a history of smoking country tobacco habitually, but was not addicted to alcohol. He never had had any pain in the ulcer since it had become indolent.

There was no evidence of disease in any of the systems; leprosy was excluded and no cause could be found to account for the ulcer. Urine was normal: pulses present in both posterior tibial arteries.

(Continued at foot of next column)

SOME UNUSUAL ACUTE ABDOMINAL CONDITIONS

By P. N. RAY, B.A., M.B. (Cal.), F.R.C.S. (Eng.)
Honorary Junior Visiting Surgeon, Medical College
Hospitals, Calcutta

It is intended in this paper to consider a few acute abdominal conditions that the practitioner may encounter and to record a few examples of conditions, some of them unusual, that demand immediate surgical intervention, but the writer does not propose to deal comprehensively with this very important subject.

I. Strangulated herniæ

The classical injunction to examine all the hernial orifices first in cases of acute intestinal obstruction is still unfortunately very often forgotten. It is necessary to remember that a strangulated external hernia is the ætiological factor in nearly 50 per cent of all cases of intestinal obstruction. Neoplasms are responsible for 10 per cent, with bands and adhesions, intussusceptions and volvuli coming next in frequency (McIver, 1932). What is very regrettable, is the frequent injudicious use of

(Continued from previous column)

Temperatures before and after T. A. B. inoculation

	Before	After
Left foot	34.5°C.	39.5°C.
Mouth	36.9°C.	38.2°C.
Ward	34.5°C.	34°C.

Here one was faced with a case presenting no single indication for a lumbar ganglionectomy. Even if the vasomotor index were valueless yet one could not get over the fact of a pulsating posterior tibial artery. The patient however insisted that an operation be done to heal his ulcer, and when it was pointed out to him that the operation must be an abdominal one he still insisted.

Operation.—With some misgiving, on the 17th June, I performed a lumbar ganglionectomy, under spinal anaesthesia, exposing the chain through the ordinary kidney incision. The exposure was excellent and the ganglia and intervening cord were easily dissected out.

On the 2nd July the ulcer on the plantar aspect of the left great toe had completely healed and the patient was discharged.

One concludes, therefore, that if treated early and by a bilateral ganglionectomy, because the disease is bilateral, much benefit would accrue to these patients; though the benefit would not be lasting, yet a longer period of useful life would be opened to them, and, further, one would suggest that in India the decision to operate be based on clinical findings and not on tests designed to prove that vasospasm is present.

REFERENCE

Telford, E. D., and Stopford, J. S. B. (1935). *Brit. Med. Journ.*, Vol. I, p. 863.

taxis, which may end in a tragedy. The following case provides an apt illustration:

Case I. Reductio en masse and rupture of sac:—

A male patient, aged 26, was admitted into the hospital for an acute abdomen. The history was as follows: the patient had a reducible right inguinal hernia for many years. Three days ago, it suddenly became irreducible, giving rise to severe abdominal pain and vomiting. It was, however, reduced by manipulation. Since then, he had been suffering, in addition, from absolute constipation. On local and rectal examination, a tense cystic swelling was found to occupy the right iliac and hypogastric regions. The seriousness of the condition was discovered during the operation. The hernia was found to have been reduced *en masse* and through a tear in the inner and posterior part of the sac, several coils of gut and omentum had escaped into the pelvic cavity, which contained a quantity of sero-anguineous fluid. A small perforation was present in a loop of gut contained within the sac and it was repaired without any difficulty. The patient made a satisfactory recovery.

The incidence of *reductio en masse* is about 0.6 per cent and it has a mortality of nearly 75 per cent, as a resection will be necessary in most cases (Frankau, 1931). In the present case, probably the rupture of the sac prevented extensive gangrene of the strangulated gut.

Case II. Simultaneous strangulation of femoral and inguinal hernia:—

A male patient, aged 32, was admitted into the hospital with a strangulated hernia. The clinical history was obtained that he was subject to an irreducible right inguinal hernia for many years and that he had two previous attacks of intestinal obstruction, which cleared up after administration of enemata and a few days of rest in bed. On local examination, a very large and tense irreducible inguinal hernia was noticed on the right side. Another small tender lump was present in the femoral region and was diagnosed as an irreducible femoral hernia. Lothiesen's incision was made and when the inguinal sac was opened, the femoral hernia happened to be spontaneously reduced. The contents of the inguinal sac were carefully examined, the coils of small intestines were found to be healthy, but adherent omentum was excised. The peritoneum was opened and the contents of the femoral hernia were carefully looked for. A knuckle of gut was discovered, showing the crescentic anemic impression of a Richter's hernia. The patient made an uneventful recovery.

Such cases are fortunately very rare. In a series of 1,500 cases of strangulated hernia, one case was reported by Frankau (*loc. cit.*) in which strangulation had occurred in both the femoral and inguinal hernia. It is possible but not certain that the previous attacks of obstruction in this case were due to obstruction or strangulation of the femoral hernia. The radical operation was performed for both the conditions, i.e., a Bassini's operation was combined with Lothiesen's.

Internal strangulation.—We are familiar with the many varieties of this condition—by bands or adhesions, or into the various peritoneal fossae. The following case may be worthy of record:

Case III. Hernia into the inferior ileo-caecal fossa:—

The patient, aged 35, a chauffeur, was recently admitted into the Medical College Hospital for acute intestinal obstruction. The history was as follows: the patient had a reducible right inguinal hernia of

many years' duration; a few hours previous to his admission into the hospital, he was nearly involved in a motor accident. He had to pull his car up in an emergency and as a result he was somewhat shaken; he was seized with severe abdominal pain, although he noticed that his hernia had been spontaneously reduced. On local examination, a tense fluctuant swelling was found to occupy the right iliac and hypogastric regions, the inguinal canal was clear, but there was no impulse on coughing. On abdominal section, a tense and strangulated internal hernia was discovered, occupying the inferior ileo-caecal fossa. Some difficulty was experienced in its reduction but it was possible to obliterate the cavity by means of interrupted catgut sutures. The patient made an uneventful recovery.

The occurrence of internal strangulation is not rare after abdominal injuries, but the present case is certainly of a very unusual type. The sudden strain of pulling up a speeding automobile would give rise to sudden contraction of the abdominal muscles. It is therefore conceivable that the forcible descent of some more coils of gut might easily give rise to strangulation of the hernial contents. On the contrary, it would be very difficult to explain in this case the mechanism of the spontaneous reduction of the inguinal hernia and the simultaneous occurrence of an internal hernia with immediate strangulation.

II. Acute perforation of peptic ulcers

In the management of emergencies in connection with gastric and duodenal ulcers, a great deal of difficulty has to be encountered at all times. As a rule, these cases come under the generic term of 'bad surgical risks', particularly in this country, because the patient is seldom taken to the hospital at an early stage. Clinically, acute perforation is characterized by the sudden onset of acute abdominal pain, especially in the epigastrium, associated with board-like upper abdominal rigidity. Clinically, three stages can usually be distinguished. The *first stage* is often regarded as one of shock, but shock does not usually supervene within an hour or two of the occurrence of the perforation. There is neither any increase of pulse rate nor fall of blood pressure. This stage may therefore be correctly described as that of prostration (Moynihan, 1926). It may completely pass off within a few hours. This painless interlude may be aptly described as the *stage of delusion* and may give rise to serious difficulties in diagnosis. The *third stage of peritonitis* sets in within 18 to 24 hours. It may be impossible to make a correct diagnosis in every case owing to (1) a good history not being available, (2) the site and character of the initial pain having been missed, (3) the unreliability of the obliteration of liver dullness, and (4) omission of a rectal examination. Careful and systematic percussion may be of the greatest value in such cases. Starting over a part that is obviously not tender, e.g., the thorax, percussion is carefully conducted towards the epigastric region. Deep perc. is resorted to if no tenderness is elic.

Operation.—On 13th February, under open ether, incision made on right side as for exposure of the ureter. The sympathetic chain was readily demonstrated and numbers 1 to 4 lumbar ganglia with the intervening chain resected.

After operation but on the same day the temperatures were:—

Thigh—36°C.
Foot—34°C.

On the 16th February, these were the same.

On the 23rd February, the patient stated that the pain in the leg had gone, but that pain in the gangrenous toe persisted to some extent, and as the toe was separating very slowly it was amputated and the patient discharged on the 16th March, 1935.

The pulse did not return in the posterior tibial artery, but with improvement in collateral circulation relief was very marked. In the region of the gangrenous toe, where degenerative changes had occurred in the vessels, improvement could not be expected.

Case 2.—Male, aged 25 years; admitted to hospital on the 5th March, complaining of pain in the left great toe and of an ulcer, which refused to heal, on the same digit.

The condition commenced five months ago, the pain being severe enough to keep him awake at night. Soon after the onset of pain an ulcer appeared on the dorsum of the great toe. The pain became progressively worse and the ulcer spread to such an extent that the terminal phalanx of the toe had to be removed in the outpatient department on the 3rd March.

Though a Mohammedan, he gave a history of smoking 5 or 6 cigarettes a day. He denied any addiction to alcohol and there was no history or evidence of venereal disease.

The region of the ulcer was exquisitely tender to the touch: pulsation in both femorals was vigorous, in the popliteals feeble, and in the posterior tibial and dorsalis pedis absent. Urine was normal. Blood sugar 0.083 per cent. Wassermann and Kahn—negative.

Temperatures before and after T. A. B. inoculation

	Before	After
Left foot ..	32.5°C	36°C.
Mouth ..	36.4°C.	39.4°C.

Operation.—On the 18th March, under open ether, a kidney incision extending from the angle of the ribs with the erector spinae to one inch in front of the anterior superior spine was made.

The exposure was not so good as with the 'ureter' incision of the first case and the demonstration of the various branches of the sympathetic was not so easily carried out.

After operation, but on the same day, the temperatures were:—

Left foot—32.5°C
Mouth—36.8°C.

On the 20th April, the patient stated that the pain in his left great toe had gone. The ulcer soon began to show signs of healing and, as he was apparently satisfied with the results of the operation, he left the hospital on his own accord.

Case 3.—Male, aged 40 years; admitted to hospital on the 28th May, complaining of the presence of an ulcer on the under surface of his left great toe, which had persisted for over one year.

He gave a history of smoking country tobacco habitually, but was not addicted to alcohol. He never had had any pain in the ulcer since it had become indolent.

There was no evidence of disease in any of the systems; leprosy was excluded and no cause could be found to account for the ulcer. Urine was normal: pulses present in both posterior tibial arteries.

SOME UNUSUAL ACUTE ABDOMINAL CONDITIONS

By P. N. RAY, B.A., M.B. (Cal.), F.R.C.S. (Eng.)
Honorary Junior Visiting Surgeon, Medical College
Hospitals, Calcutta

It is intended in this paper to consider a few acute abdominal conditions that the practitioner may encounter and to record a few examples of conditions, some of them unusual, that demand immediate surgical intervention, but the writer does not propose to deal comprehensively with this very important subject.

1. Strangulated herniæ

The classical injunction to examine all the hernial orifices first in cases of acute intestinal obstruction is still unfortunately very often forgotten. It is necessary to remember that a strangulated external hernia is the ætiological factor in nearly 50 per cent of all cases of intestinal obstruction. Neoplasms are responsible for 10 per cent, with bands and adhesions, intussusceptions and volvuli coming next in frequency (McIver, 1932). What is very regrettable, is the frequent injudicious use of

(Continued from previous column)

Temperatures before and after T. A. B. inoculation

	Before	After
Left foot ..	34.5°C.	39.5°C.
Mouth ..	36.9°C.	38.2°C.
Ward ..	34.5°C.	34°C.

Here one was faced with a case presenting no single indication for a lumbar ganglionectomy. Even if the vasomotor index were valueless yet one could not get over the fact of a pulsating posterior tibial artery. The patient however insisted that an operation be done to heal his ulcer, and when it was pointed out to him that the operation must be an abdominal one he still insisted.

Operation.—With some misgiving, on the 17th June, I performed a lumbar ganglionectomy, under spinal anaesthesia, exposing the chain through the ordinary kidney incision. The exposure was excellent and the ganglia and intervening cord were easily dissected out.

On the 2nd July the ulcer on the plantar aspect of the left great toe had completely healed and the patient was discharged.

One concludes, therefore, that if treated early and by a bilateral ganglionectomy, because the disease is bilateral, much benefit would accrue to these patients; though the benefit would not be lasting, yet a longer period of useful life would be opened to them, and, further, one would suggest that in India the decision to operate be based on clinical findings and not on tests designed to prove that vasospasm is present.

three effective motions. Paralysis of the intestines occurred subsequently but with the onset of peritonitis.

IV. Volvulus

The two following cases of volvulus appear to be sufficiently unusual to merit record:

Case VII. Compound volvulus of caecum and jejunum:—

The patient, a man of 22, was admitted into the hospital for acute intestinal obstruction of three days' duration. The pain was, at first, mainly complained of near the umbilicus, but after a few hours, with increasing distension, it spread all over the abdomen. On abdominal examination, a definite fluctuant resonant tumour, measuring nearly 9 inches by 5 inches, was found to occupy the left half of the upper abdomen. A high paramedian incision was made on the left side and an enormously ballooned coil of the large intestine was discovered. It proved to be the caecum and the proximal part of the ascending colon. It was necessary to puncture the gut before it could be untwisted. On either side, there was an irregular peritoneal tear measuring about 6 inches in length, but owing to the presence of an unusually long mesentery with which the caecum was provided, these were completely peritonized without any difficulty. It was further discovered that the volvulus was entwined with a distended coil of jejunum, which occupied the right iliac fossa. The patient made an uneventful recovery.

Volvulus of the caecum is far commoner than is generally considered, but a compound volvulus of the caecum and jejunum is certainly rare. It is not uncommon for the distended caecum to travel upwards and to the left, behind the root of the mesentery and towards the spleen. In this instance, it occupied the left lumbar and hypochondriac regions and resembled an enlarged cystic kidney. The distended jejunal loop occupied the right iliac fossa. After peritonizing the linear peritoneal tears and insertion of three layers of Lambert's sutures, the mobility of the caecum was limited to such an extent that no further plication or fixation was deemed necessary.

Case VIII. Sigmoid volvulus containing a tapeworm:—

The patient, an old man of 64, was admitted into the hospital for acute intestinal obstruction of five days' duration. On examination, the patient looked very ill and emaciated, and the abdomen was enormously distended. After abdominal section, the distended coils of gut were untwisted with some difficulty. I discovered a definitely palpable elongated band within the lumen of the gut along its long axis. Sigmoidostomy was performed and it was found to be a tapeworm. A Jaque's catheter (no. 12) was tied in. The patient made an uneventful recovery. The catheter came out on the fifth day, and the sigmoidostomy closed spontaneously. It is of interest to note that the tapeworm was not expelled during the post-operative period. Presumably it survived the strangulation. Having narrowly escaped three major calamities, *viz*, the great earthquake, the monsoon floods, and the volvulus at the age of 64 and all within the brief period of 9 months, the patient, a firm believer in fate, refused to bother about the lesser evil of a tapeworm. He was anxious to go back and build up a new home. He was accordingly discharged at his own request.

The discovery of a tapeworm is of rare occurrence in emergency abdominal surgery. The patient, being a Mohammedan, would not touch

pork; the worm was, therefore, presumably a *Tania saginata*. It is not improbable that the parasite was mainly responsible for the causation of the volvulus. The survival of the parasite in a volvulus of five days' duration is of interest. Sigmoidostomy was performed for the inspection of the parasite during the operation, relief of distension and prevention of subsequent recurrence of the volvulus.

V. Acute abdomen in children

It is not necessary to emphasize the gravity of acute abdominal conditions in infancy and childhood. Apart from intussusception, acute appendicitis may be justly regarded as the most important abdominal lesion in childhood. In my experience, the former is nearly four times as frequent as the latter in children under 3 years of age.

(a) *Acute appendicitis*.—The classical signs and symptoms may be present in acute appendicitis in children, but, if these are rigidly insisted upon before making a diagnosis, many serious cases will be missed, because abdominal rigidity and changes in pulse or temperature may be absent and the history may be misleading. The greatest difficulty may be encountered in the pelvic or high appendix. Tenderness on rectal examination and suprapubic pain in the former are significant points. The high appendix may simulate gastro-enteritis or duodenal ulcer. Even the greatest clinician is apt to be at fault in such cases. What is true of the adult patient is equally true of the child: patients never died of appendicitis, they died of its treatment (Moynihan, 1933). All acute appendicitis is obstructive, and if no aperient treatment were given no case would ever become really active. There was never a gangrenous perforated appendix, in which an aperient had not been given. Unfortunately, in our experience, it is an exception to see a child, who has not been given one or more purgatives, before he is brought to the hospital for operative treatment. Lord Moynihan (1933) is of opinion that no child should be left alone with his appendix for half an hour. Whatever the surgeon might feel about the prognosis, he must inevitably and without exception operate, if an aperient had been given. If not, the best conditions might be sought even at the price of some delay. In every case treatment whether medical or surgical must have its basis in a just appreciation of pathology. Without this appreciation the best technique may fail (Ryle and Rayner, 1932). If the surgeon is wrong and finds that he has removed a normal appendix, the mortality should be *nil* (Crymble, 1935). In doubtful cases, where basal pneumonia, pleurisy, or pneumococcal peritonitis is suspected, it is advisable to wait until the diagnosis is cleared up.

(b) *Pneumococcal peritonitis*.—Fortunately pneumococcal peritonitis is a rare condition. It

Therefore in the low plains during the hot weather not a single case of fresh infection of the human host can or does take place, and every one that is seen is the relapse of a previous infection at another season. Similarly, in the high hills also there can be no fresh cases of human infection, and the few that occur are relapses due to the cold.

While there is thus no new malaria in the hot months either in the low plains or high hills, in the intervening area matters are different and there is some fresh malaria. One finds an ever-decreasing relapse rate and an increasing new human infection rate, as one ascends from the low plains to the high hills; this depends wholly or partly on the rate of infection in the mosquito increasing up to a point in the area where the physical conditions (of which a moderate temperature is most important) are at an optimum (these conditions approximating to those of the low plains during the cold weather as mentioned above).

A little evidence on the matter is available. Thus (a) Strickland, Chowdhury and Chaudhuri (1933) found a natural sporozoite rate of 3.66 per cent during April and May in wild mosquitoes at Siliguri at the foot of the hills, a condition unlike that of Calcutta with a sporozoite rate of zero at this season; and (b) at Ambootia near Kurseong at about 3,000 feet, as the annual epidemic is in April and May while there are only sporadic cases in September and October, one can take it that the April and May infections are original infections and not relapses. There is thus in the intervening area a definite infection at this season, and generally speaking the 1,600-foot line appears, from a survey of the epidemic seasons in different places in the low valleys, to be that up to which original infection is increasing in the hot spring months and above which it decreases.

Now, while, as stated above, in the low plains November to January is the season of greatest infection in the mosquito, September and October being the months when the greatest numbers of new human infections are taking place, in the high hills there are no cases of new infection, so at this season there is a gradual decline in the infection rate all the way from the low plains up into the hills.

Travellers in the hills then in the spring (the hot months of the low plains) should keep as low in the valleys as possible until they can dash up over the 1,600-foot line and as high as possible. In the autumn (at the end of the rains) they should keep up as high as possible all the time.

As for new settlement, the site of election should be as high above 1,600 feet as possible.

Summary

All cases of malaria during the hot months in the low plains are relapses, or a manifestation of an earlier infection, probably due to

heat, while at this season in the low hills they are, at any rate in part, primary infections: in the high hills the few cases arising are relapses probably due to cold. At this season then the lower the altitude the less the chance of infection, but this only applies to the tract below about the 1,600-foot contour, which is the putative line of greatest infection: above this line the infection rate declines owing to increasing cold.

The primary infections in the spring in the low hills rarely relapse in the cold weather, confirming the experience of the benefit of sending 'malaria cases' to a cold climate. Apparently excessive heat is the usual cause of relapse.

In the autumn months (as one ascends from the low plains up to the high hills) there is a gradual decline in the fresh infection rate, owing to the increasing cold increasingly inhibiting the infection of mosquitoes and their development.

A Mirror of Hospital Practice

A CASE OF MINOR EPILEPSY (*PETIT MAL*) DUE TO CEREBRAL TRAUMA

By OWEN BERKELEY-HILL
LIEUTENANT-COLONEL, I.M.S. (Retd.)
Ranchi

L. J. J. MUSKENS, in his noteworthy book on epilepsy, observes that traumatic epilepsy falls into a special group among the epilepsies. Further, he calls attention to a very important point in connection with so-called traumatic epilepsy, namely, that one should be very cautious in ascribing the fits to a cranial injury even when a definite scar exists on the head of the patient in the left parietal region. Muskens would go so far as to advise against any diagnosis of epilepsy due to trauma except on the evidence of a skiagram or an actual operation or a *post-mortem* examination. Only in such circumstances as these, Muskens believes, is one justified in attributing epilepsy to a head injury.

The following case is interesting from the ætiological standpoint because the disturbance

of the cerebral function of the patient was definitely established by a surgical operation which was performed with the view of relieving the fits.

The patient is a girl (Anglo-Indian), aged 18. She is the eldest of three children. She was a full-time child and was healthy at birth. Labour was normal. She was breast fed. She walked after nine months and talked after one year. At the age of three and a half she fell twenty feet on to a flower pot and sustained a fracture of her skull. Immediately after the accident she is reported to have shown signs of 'tetanus'. She was taken at once to the Prince of Wales' hospital, Calcutta, and admitted. On admission she was unconscious. She is reported to have vomited twice. No bleeding was observed from either the nose, mouth or ears. No skiagram was taken as she was very restless. She was given anti-tetanic serum and discharged after one week as 'cured'. From that time on the patient has suffered from repeated attacks involving disturbances in her speech accompanied by a partial loss of consciousness. As there are no other disturbances than these, there is always a great likelihood of an attack passing unnoticed should it come on when the patient did not happen at the time to be speaking. If, however, she was in the act of speaking when the attack came on, she would break off in the middle of a sentence and repeat the last word uttered several times over or begin to whistle. It appears that no attempt was ever made to keep an accurate register of the number of attacks she would have in one day. All that her mother can say is that sometimes she would have 'very many' while at others only 'a few'. No day passed without at least one attack. At the age of 13 she was trephined and some pieces of bone removed. No improvement followed this operation; the attacks continued exactly as before. The patient says she knows when an attack is coming but she cannot describe the aura. When an attack has passed off she has no recollection of it having occurred. She cannot evoke an attack by will. Beyond being somewhat tall for her age and rather 'weedy', there is nothing else wrong with the patient. She is backward for her age in regard to scholastic attainments since she was taken away from school at an early age on account of her illness. As is so often the case with patients suffering from epilepsy, she has been prevented from acquiring the ordinary accomplishments of a girl of her type. She cannot ride a bicycle nor swim nor play any outdoor games. For this reason her physique has suffered and she feels inferior to other girls of her own age and standing. Many of the usual drugs have been prescribed from time to time but without any success in relieving the symptoms. It would appear that a real amelioration can only follow treatment on surgical lines.

Muskens, in his book to which allusion has already been made, cites a case very similar to the one under consideration. His patient fell from the third story of a house on to a clothes prop when she was 3 years of age. As a result of this fall she sustained an injury to her skull which left a depression on the left side of the calvarium over the parietal region. She was immediately operated on. After the operation she began to have unilateral epileptic fits. When 13 years old she was operated on again with temporary improvement. Some years later she underwent a fourth operation but no improvement followed. At the age of 22 another operation was recommended as the fits had become bilateral. The operation was not performed as it was feared that the fits, which

had become very numerous, would get worse. A year later she was operated on for the fifth time and a deformed piece of bone, that had been left over in the former operations, was removed. No improvement followed. After six weeks she was operated on for the sixth time. This time the dura mater was freely exposed and a macerated opening was found in it. Just inside the opening two small splinters of vitreous lamina were discovered lying on the cerebral cortex. They were removed. No improvement followed. Finally the patient underwent yet another operation in which the brain was exposed as before and a weak faradic stimulation was applied with a bipolar electrode to that part of the cortex. It was found that epileptic fits could be induced by stimulation of certain definite areas of the cortex. These areas were carefully removed with a spoon to a depth of 4 millimetres and the wound closed. The patient has remained free from fits for seventeen years. She has married and has given birth to healthy children and suffers from no mental incapacity whatsoever.

This history is very instructive both from the surgical and the neurological aspect. Among other points, it emphasizes the importance of the use of the faradic current for diagnosis. No doubt much experience is required before the method can be used with success. I have little doubt that could a surgeon be found who possesses the necessary experience and could my patient be persuaded to undergo another operation, she might very easily obtain permanent relief from her symptoms. It should however be borne in mind that in traumatic epilepsy a cranial operation is only part of the treatment for the operation merely removes one of the conditions which facilitate the development of chronic epilepsy. Several factors may play a part and among other things great care must be taken that digestive disturbances do not arise and that constipation is avoided. If found necessary, drugs may be administered but only under supervision. Personal cleanliness down to the smallest detail of the care of the teeth or artificial dentures, careful supervision of the diet, total abstention from alcohol, rest, open air, regulated exercises as well as definite psychical encouragement, are all prophylactic measures of serious import. Lastly, it is important to remember that the prognosis of *petit mal* is not so good as in the case of severe fits. The explanation of this may lie in the hypothesis, assuming it to be correct, that *petit mal* attacks are not sufficient to dissipate the toxins, the accumulation of which induces the fit. Cases that suffer, on the other hand, from severe fits often describe a feeling of unusual well-being after a fit for the accumulated toxins have been thoroughly dissipated by the fit. Further support of this contention is derived from experiments carried out on cats through the administration of camphor and other drugs.

Considerations of this sort, however, should in no way preclude surgical treatment in definite cases of epilepsy due to cerebral trauma, no matter what may be the nature of the fits.

-A CASE OF HYDROPHOBIA WITH THE LONGEST INCUBATION PERIOD ON RECORD

By K. R. K. IYENGAR

MAJOR, I.M.S.

*Director, Pasteur Institute of Southern India,
Coonoor*

A. K. B., MALE CHILD, aged 10½ years, son of Mr. A. K. M., Bangalore, was brought to the institute at 11-45 a.m. on 15th June, 1935, from Bangalore.

History of the case.—On 20th March, 1932, at 7 a.m. the boy was bitten by a street dog which entered into the house, inflicted the wounds on him and ran away; further whereabouts of the animal not known. Other persons or animals bitten by the dog not known.

The parents and the patient are quite certain (on repeated questioning) that there was no subsequent bite by dogs, cats, mongooses or any other suspected rabid animals. Infection from drinking unboiled milk was excluded. The parents are well educated and belong to a highly respectable family.

For some months after this incident, it is said that the boy was very much afraid of dogs; later, he used to play with two dogs reared by one of his relatives and these dogs are reported to be alive and quite healthy.

The boy was bitten on the right side of the chest through clothing and was scratched on the dorsum of left hand on the bare skin. A small scar on the right anterior axillary margin and a scar 1½ inches long running down from the right nipple were visible. These two scars were said to have been due to the bite of the dog. (The parents and the patient, on repeated questioning, definitely say that there were two wounds on the chest while on the history card of this patient, it is written that there was only one wound on the chest.) No scars are visible on the left hand, but it is mentioned in the history card that there were two wounds on the left hand.

On the history card it is mentioned that the wounds were not cauterized, but the father of the patient now says that he took the boy immediately after the bite to a medical practitioner who cauterized the wounds within half an hour of the injury, but the actual agent used for cauterization is not known to him.

The boy underwent a full course of antirabic treatment then in vogue (1 per cent carbolic sheep vaccine, 5 c.cm. daily for 14 days, irrespective of the age of patients and classification of wounds) at the Bangalore Cantonment treatment centre, from 22nd March to 5th April, 1932. He took the 14 injections in 15 days, having been absent for one day during the course. After six months, the boy was reported to be alive and healthy.

Present complaint.—On 11th June, 1935, the boy complained of pain in both the scars on the right chest, the sites of the original bites in 1932. The pain gradually increased and was felt in the whole of right arm and right chest.

On the night of the 12th June, he had a few spasms of the muscles of the neck.

On 13th June, spasms of the neck muscles gradually increased in severity and frequency. In the evening, he complained of difficulty in swallowing water and this condition gradually got worse.

On 14th June, the patient was taken from Bangalore by train to Coonoor, and he arrived at the institute at 11-45 a.m. on 15th June.

Condition on admission.—The boy was very much excited. He shouted and screamed at the sight of

strangers (the staff of the institute) and also at any sudden noise. The characteristic stare was apparent. He was very restless and talkative, tossing about and jumping out of the bed. Spasms of the neck muscles occurred frequently. Severe spasms of throat muscles at the sight of water in a tumbler was observed. Even at the mere mention of 'water' (when the patient's mother asked for some to drink) these spasms occurred. The patient complained of thirst, but dared not attempt to drink water, due to the spasms. Unable to take food. Moderate salivation present. Bowels moved on 14th June evening. Urine passed freely on arrival at the institute. Pulse rapid, 110 per minute. Owing to the restless and excited condition of the patient, the temperature could not be taken, but the body felt warm to the touch.

15th June, 1935.

12-15 p.m. Morphine sulphate ½ grain hypodermically.

2-15 p.m. Still in the same excited and restless condition. ½ grain morphia repeated.

5-30 p.m. Still restless and tossing about and jumping up in the bed. Spasms of the muscles, almost of the entire body, occurred very frequently, accompanied by screaming. Incoherent and noisy, talks as in delirium. Profuse salivation present. Took two small sips of coffee with great difficulty. Pulse rapid, 130 per minute. Morphia ½ grain repeated. Glycerine boracic was applied to the lips.

7 p.m. The patient was quiet, and in an exhausted condition. Pulse very feeble.

8 p.m. The patient expired.

Diagnosis.—Hydrophobia.

Date of bite.—20th March, 1932.

Date of first symptoms of illness.—11th June, 1935.

Incubation period.—3 years, 2 months and 21 days (1,176 days).

Days of illness.—4 (96 hours).

Date of death.—15th June, 1935.

Period from date of bite to death.—3 years, 2 months and 25 days (1,180 days).

Comments.—The incubation period is the longest on record. Some have noted very long incubation periods in exceptional cases after protective inoculation—1½ to 2½ years—after excluding all possibilities of new infection in the interval. The only possible explanation that can be offered is that the virus was lying dormant after antirabic treatment, until it was roused to activity by some cause. Fortunately, such cases are exceptional.

TREATMENT OF NEURITIS WITH VACCINEURIN

By J. N. ROY, M.B.

and

H. K. SAHA, M.B.

(From the Carmichael Medical College, Calcutta)

THE patient M. D., Hindu female aged 40 years, was admitted into the hospital with the following complaints:—

Palpitation—2 months' duration.

Burning sensation all over the body—1 month's duration.

Pricking pain in hands and legs—1 month's duration.
Inability to walk—1 month's duration.

Mucus diarrhoea, passing 6 to 8 motions in a day—15 days' duration.

History of onset.—The patient says that about one month previously, after an attack of malaria which lasted a few days, she felt an intense pain on the right side of her chest while eating. Later it developed into a burning sensation spreading all over the body. After a few days' treatment it diminished, but pain and burning sensation over the ankle, small joints of lower extremities, wrist and hands persisted. The pain used to suddenly become severe and very frequently she had cramps in her muscles.

Personal history.—Mother of two children. No history of abortion, periods—regular. Admits history of syphilis and gonorrhoea and was treated for syphilis five years previously.

Family history.—Nothing particular.

Past history.—A few years previously she suffered from oedema of legs with pain in the limbs.

General survey.—An adult female of short stature and thin musculature with hands and legs atrophied.

Pulse—96 per minute; volume—moderate; tension—low and regular; respiration—20 per minute and the temperature—98.4°F.

Examination of nervous system.—Higher functions and cranial nerves—normal.

Sensory functions.—Hyperæsthesia and hyperalgesia all over the body particularly over the lower limbs (beginning from the ankles and wrists respectively and extending upwards), the deep-seated tenderness was much exaggerated, especially in the calves. Other types of sensation were not affected.

Motor functions.—Paresis of muscles in upper and lower limbs more marked in the latter (this also began from the ankles and wrists respectively and extended upwards). Slight atrophy of muscles in the affected region; the extensors were more affected than the flexors. There was inability to raise the legs, and the muscles were flaccid. No abnormal muscular movement was observed.

Reflexes.—Superficial—abdominal—present.

	plantar—flexor response.
Deep—	ankle—absent.
	knee—diminished.
	adductor—present.
	triceps—present.
	biceps—present.
	supinator—absent.
Clonus—	ankle and patellar—absent.

Organic reflexes.—normal.

Vasomotor and trophic.—redness and pitting on pressure in the distal portion of lower limbs.

Skin.—glossy, no eruptions present.

Digestive system.—liver palpable, 2 inches below costal margin.

Abdomen.—hard, not tender.

spleen just palpable, moderately hard.

Other systems.—nothing of importance.

Laboratory findings.—Blood examination. Hæmoglobin—70 per cent, red blood cells—3,440,000, white blood cells—7,500, polymorphonuclears—70 per cent, lymphocytes—24 per cent, monocytes—2 per cent and eosinophils—4 per cent. Wassermann reaction—negative and Kahn—doubtful.

Stools.—normal and contained no ova or protozoa.

Urine examination report.—Normal except for a few pus cells and numerous epithelial cells.

Treatment and progress of the case.—Just after admission, the patient was given an antisyphilitic mixture. On the third day after admission injection of vaccineurin series 1 was begun, one ampoule every alternate day, strictly following the directions given by the makers. The patient began to improve after the completion of series 1 and the next two series of injections were given, the patient improving all the time.

The patient was kept in hospital for 42 days; on the twenty-second day of her stay, she had a sharp rise of temperature and quinine was administered. The temperature came down, but again she had a similar rise of temperature on the twenty-fifth and twenty-seventh days, after which she remained afebrile and kept good health.

At the end of series 2, she began to walk a little and could walk freely at the end of series 3 of the course. When she was discharged from hospital, she was relieved of her pain and hyperæsthesia almost completely and her general appearance had become nearly normal, from a condition which at first appeared to be hopeless and incurable.

Remarks.—This is the second case of peripheral neuritis in which we have been able to complete the full course of vaccineurin injections, and get such encouraging results.

We have used this drug in sciatica and trigeminal neuralgia with remarkable results, and we are trying it on other nervous cases.

Disadvantages of treatment.—The treatment is tiresome, as there are three series of injections of six ampoules each, i.e., eighteen injections, and the number of days actually required for completion of the whole course is 35 days.

The price is high. Finally these patients are neurotic and find difficulty in waiting for the full course of treatment with patience.

A CASE OF REVEALED ACCIDENTAL HÆMORRHAGE

By R. G. VANCHESWARA IYER, L.M.P.

Civil Hospital, Thongwa

M. S. M., a Burmese female, aged 38, an eighth para in the eighth month of her pregnancy, suddenly started discharging blood at about 2-30 a.m. on the morning of 6th April, 1935. She had gone to bed the previous evening in a perfectly good state of health, and woke up suddenly at about 2-30 a.m. with a desire to micturate. On standing up blood commenced to flow from the vagina and getting alarmed about her condition she sent for the Municipal Results System Midwife. The midwife finding the condition beyond her sent for me. I saw the patient for the first time at 3 a.m. on the 6th April, 1935. She was lying on a bamboo mat on the floor of her house and blood was escaping from her vagina leaking through the floor and gathering on the ground underneath. She must have lost about one pint of blood by this time. I made a vaginal examination and found that the os admitted two fingers. No difficulty was experienced in excluding placenta prævia as no placenta was felt either centrally or marginally through the os. The presenting part was not fixed in the pelvic brim and I felt certain that the head was not presenting. I diagnosed the condition as revealed accidental hæmorrhage and had the patient removed to the hospital in a cradle. Despite the loss of blood the patient's general condition was not as yet serious. The pulse was only 64 per minute. I decided to plug the vagina and being short of cotton-wool sterilized strips of gauze, rolled into balls of convenient size, were used to plug the vagina tightly, starting from the posterior fornix. The woman complained of pain when the plugs were rammed well round the cervix. A 'T' bandage was applied and the patient put to bed. I gave her a hypodermic injection of morphine sulphate $\frac{1}{2}$ grain and atropine sulphate $\frac{1}{75}$ th grain and ordered a mixture containing calcium chloride grs. 10 to be given every hour for the next

six hours. It was 4 a.m. when I completed the plugging and hypodermic injection. Notwithstanding the morphine injection the patient did not sleep. At 7 a.m. her pulse rate was 100 per minute. There was no complaint of abdominal pain or discomfort. At 11 a.m. the patient again discharged blood although the vaginal plugs were in position. There was no pain and the uterus was not contracting. She was placed on the operating table and the plugs removed. She was bleeding profusely, and the os was dilated to admit three fingers. I ruptured the membranes and with my fingers in the uterus managed to draw down one leg and by traction succeeded in delivering a living female child. I divided the cord between two pressure-forceps, kneaded the uterus and with external manual pressure expressed the placenta. The woman had lost a large quantity of blood by now and was in a state of collapse. I gave her 1 c.cm. of pituitrin hypodermically and three vints of saline intravenously. At 3 p.m. the patient had a temperature of 101°F. and her pulse rate was 112 per minute. She complained of thirst. There was no post-partum hæmorrhage, her temperature was normal next morning and continued so throughout her stay in the hospital. Her puerperium was uneventful except that the baby died on the second day after delivery. She walked out of the hospital cured on 11th April, 1935, six days after delivery.

A CASE OF SARCOMA OF THE THIGH

By A. C. DEY, L.M.R.

Senior Resident Medical Officer, Astanga Ayurveda Hospital, Calcutta

T. S. Hindu, male, cultivator by occupation, aged 20 years, an inhabitant of the district of Midnapur, was admitted by the writer in the Astanga Ayurveda Hospital on the 2nd August, 1933, for a tumour on the left thigh.

Previous history.—About a year ago he had a fall and injured the lower third of his left thigh. A few days later he noticed a swelling on the injured part. It was painful to pressure and he had applied liniments

Fig. 1.—Before operation

and embrocations without effect. The swelling gradually increased and attained such a huge size that he was compelled to remain in bed. The patient said that he used to get febrile attacks off and on with occasional pain on the site of the tumour. The huge size of the tumour and his incapacity to do his normal

duties compelled him to come down to Calcutta for treatment.

Condition on admission.—The patient was in a very low condition. Pulse—120, and respiration—26 per minute. Temperature—100°F. The heart—apex beat was at the sixth interspace; first and second sounds were feeble. The lungs—a few scattered râles and rhonchi were present in both lungs. The liver—not palpable. The spleen was enlarged 2 inches below the costal arch.

The tumour.—It involved practically the whole of the left thigh extending from the greater trochanter to the knee joint. The length of the tumour was 21 inches and the greatest circumference 27.5 inches

Fig. 2.—After operation

The superficial chain of lymphatic glands of the left groin was enlarged.

Blood examination.—Hæmoglobin—50 per cent, red blood cells—2,700,000 per cubic millimetre and white blood cell—12,100 per cubic millimetre.

Differential count.—Polymorphonuclears—56 per cent, lymphocytes—23 per cent, large mononuclears—17 per cent, and eosinophils—4 per cent.

Considering the above circumstances, the surgeons hesitated as to whether he would stand an operation. On account of the serious condition of the patient and his repeated requests for removal of the tumour, operation was decided upon and disarticulation of the hip joint was done by Dr. S. C. Das under spinal (spino-caine) anaesthesia on 7th August, 1933.

On examination of the tumour after the operation it was found to be a mixed-celled sarcoma containing

round, oval and spindle cells and involving the soft structures of the thigh.

The patient made an uneventful recovery except for a few post-operative complications and was discharged cured on the 27th September, 1933. As far as information could be obtained by the writer the patient is still alive and is in good health.

Points of interest in this case are :—

1. Huge size.
2. Absence of metastases.
3. The patient is still alive, though the operation was done a year and a half ago.

In conclusion I am grateful to my visiting surgeon Dr. D. P. Ghosh, for permission to publish the notes of this case.

A CLINICAL CASE OF PULMONARY TUBERCULOSIS

(COMPLETE RECOVERY FOLLOWING PNEUMOTHORAX TREATMENT EVEN IN A CASE WITH CAVITATION)

By N. R. NADIG, L.C.P.S. (Bom.)
Hubli, Dharwar District

The patient, a male of thirty-six, had extensive tuberculous infiltration in the left lung; x-ray examination suggested the presence of two large cavities in the upper and middle part of the left lung, and also slight tuberculous infiltration of the apex of the right lung which appeared to show a tendency towards fibrosis.

The hilar shadows were enlarged on both sides suggesting the presence of calcified tuberculous glands. The heart and aorta were normal.

On admission the patient had all the usual constitutional symptoms, *viz.*, temperature, cough, expectoration, and night sweats.

I decided to induce artificial pneumothorax in his left pleural cavity with the idea of compressing the two large cavities, after giving him complete rest in bed for a fortnight.

The patient came to me on 1st October, 1934, and was given the primary air injection of 350 c.c.m. on the 15th. The pleural cavity showed a well-marked negative pressure. A refill of 400 c.c.m. was given on the 18th October.

On screening the patient on the same day the picture showed a fairly good collapse of the lung, which appeared like a flattened band, against the hilum. The cavities were also partially compressed.

The refills were given once a week at this stage.

The patient gradually showed alleviation of his symptoms—he had slight expectoration and fever, and he increased about twenty pounds in weight in two months.

In December the patient started walking a little and at present he walks about two miles a day without the least difficulty and without showing any constitutional symptoms.

He is now taking his refills at an interval of a fortnight and has resumed his duties of the management of his factory.

Conclusion.—My reason for describing this case is to show that pneumothorax treatment may be employed not only in early unilateral cases but also in advanced third-stage cases. No doubt there is every possibility of encountering extensive pleural adhesions at this stage, nevertheless it is advisable to try pneumothorax on such a case, and if found unsuccessful to give it up and advise some other treatment such

as thoracoplasty operation, with a view to compressing the cavities.

The immediate and remote effects of artificial pneumothorax

The immediate results that we usually see after inducing pneumothorax are often striking. In about a fortnight's time, the patient passes from a state of more-or-less profound illness into one of comparatively good health. The temperature subsides, the cough and sputum diminish, the patient regains his appetite, increases in weight, and his general health improves rapidly.

The more remote results of pneumothorax however have to be considered. These are of course much better when the treatment is given at an early stage of the disease, when the patient has good resisting power than when the disease is of long standing and the resistance has been markedly lowered.

It must be admitted however that many patients at an advanced stage can be relieved of their most distressing and obstinate symptoms and survive longer than would otherwise have been possible.

All medical men with experience of collapse therapy have had good, mediocre and bad results. They have also witnessed complete cures and these cures have been maintained for years after discontinuing the treatment.

There is a reasonable chance that artificial pneumothorax will check the activity of the disease, render the patient more comfortable, and prolong his life.

No doubt this is a therapeutic method which is capable of further improvement as knowledge advances. The indications and contra-indications should be laid down very precisely. The duration of treatment should be better understood than it is at present.

In my small experience, I have treated a sufficient number of cases, to say that the best results of artificial pneumothorax are of course obtained at an early stage of the disease of the lung, when the pleura is free from adhesions there is a sound opposite lung and a patient who is still in a fair state of general health and not totally exhausted. Even under apparently hopeless conditions the results have proved that collapse therapy is worth while.

The method is applied in the early cases in order to bring about a cure and to prevent the disease from spreading. I know of a few cases where the disease, which was unilateral, extended rapidly to the contralateral lung, in spite of open air, rest and nutritious food when efficient treatment by this method (artificial pneumothorax) might have checked the spread of the condition.

The treatment is carried out in advanced cases rather to save life than to effect a cure.

In this case an attempt at artificial pneumothorax was decided upon, only when it became

obvious that if left alone the patient would die. He is now in fairly good health and able to get about, although not fit for any strenuous work.

Conclusion

The creation of artificial pneumothorax should be used as a palliative measure in advanced cases. By this means it is possible to render the patient's life more comfortable. A complete collapse of the lung should not be attempted.

At an advanced stage with both lungs affected the worse is selected for artificial pneumothorax. Air should be injected very slowly at repeated intervals, as there is every chance of the contralateral lung being overworked on account of the extra strain put on it.

Finally it must be emphasized that artificial pneumothorax cures an early case, and it should not be considered only as a last resource. Considerable benefit is derived when extensive disease is found in both the lungs. There is everything to gain and nothing to lose and this procedure should be adopted as long as there is any hope of improvement.

AN UNUSUAL SITE FOR A HYDATID CYST

By JEMADAR MANOHAR LAL DANG, D.T.M., I.M.D.

Indian Military Hospital, Quetta

ALTHOUGH hydatid cysts may be found in any tissue of the body, the liver and lungs are by far the commonest sites.

Case history.—A Sikh carpenter, aged 23 years, first asked advice on account of a swelling the size of an almond on the left side of the neck below the angle of the jaw. The swelling had been gradually increasing in size for about eighteen months. Superficially the appearance was that of an enlarged lymph gland. There were no other enlarged glands, and on closer examination the swelling was found to extend fairly deeply, it was fairly mobile and felt cystic in consistency.

On x-ray examination there was a spherical semi-translucent tumour just below the left mandibular arch not adherent to any structures in the vicinity.

Operation.—An incision 2 inches in length was made along the anterior border of the sterno-mastoid muscle from the angle of jaw on the left side. The swelling was revealed under the platysma and deep cervical fascia lying on the submaxillary gland and adherent to it. It was the size of a hen's egg and had a pearly-white capsule. It was dissected off the submaxillary gland and was adherent to the carotid sheath. A piece of the sheath was removed along with the cyst. The wound was closed and it healed by first intention. On opening the cyst it was found to contain several daughter cysts and was a typical hydatid in appearance.

Microscopic examination of the fluid revealed a number of hooklets.

I am very grateful to Captain H. A. Ledgard, I.M.S., for conducting the operation and supplying me with notes of it and to Major D. W. M. MacKenzie, R.A.M.C., for allowing me the radiographic examination.

A CASE OF DYSENTERY CAUSED BY *BALANTIDIUM COLI*

By LAL MOHAN BANIK, L.M.T.

Assistant Medical Officer, Teok Tea Estate, Assam

A WOMAN, aged 60 years, was admitted into hospital complaining of abdominal discomfort and passage of loose stools containing blood and mucus.

The stool on naked-eye examination was semi-formed, clay-coloured and contained blood and mucus.

Under the low power of the microscope a number (about 50 per field) of oval-shaped mobile bodies could be seen in the stool preparation. Some exhibited constant rotatory movement while others in addition showed actual locomotion. A few were seen dashing in and out of the field. Under the high power the protozoa showed cilia all round, the 'mouth' at one end (also ciliated) and the two big vacuoles with numerous smaller vacuoles in the cytoplasm characteristic of *Balantidium coli*. No cyst formation was seen. One parasite attracted attention by its dumb-bell appearance. The constriction in the middle gradually grew greater and greater till division into two daughter protozoa was complete. The protozoa were found to live for about two and a half hours under the cover glass and would probably have lived longer if drying had not taken place.

As the labourers on the estate keep pigs it is highly probable that the infection originated from them.

Treatment.—Magnesium sulphate by mouth and emetine gr. $\frac{1}{2}$ daily for six days failed to have any effect. Thymol gr. 16 was also found to be useless. Finally three Yatren enemas were given (eight ounces of a 2.5 per cent solution), once on each of three consecutive days; these cleared the stools of protozoa and the patient of symptoms.

A CASE OF INFANTILE SCURVY

By D. N. CHAKRAVARTI, M.B.

Malda

A FEMALE CHILD, aged nine months, was brought to me for the following complaints:

- (i) Symmetrical swelling of both the lower extremities for about a month.
- (ii) Inability to move both the legs for the same period.
- (iii) Screaming when the parts were touched.

On examination the child looked quite healthy but was extremely apprehensive of the legs being handled. The legs were immobile, slightly flexed at the knees and the thighs were rotated outwards. The lower epiphyses of both the femurs were much enlarged and tender. One of the lower incisors was being cut and was almost through but there was neither swelling nor change of colour of the gum. There was no tendency to hæmorrhages from any part of the body nor abnormality in any other systems. There were no signs of rickets.

On inquiry into the history I learnt that the child had been fed entirely on boiled cow's milk and barley water from the 8th day of its life and mother's milk for the first seven days only. No patent food was given. The parents denied any history of syphilis.

From the history of its feeding and frequency of scurvy at this age, I diagnosed the case as one of infantile scurvy.

The child was put on orange juice two ounces a day, and baked potatoes. The potatoes were baked in the skin and the mealy parts just beneath the skin were scraped and shaken up in milk, which the child was then given. In eight days there was marked improvement.

As the family were too poor to afford orange juice I prescribed mango juice afterwards, one teaspoonful four times a day, which eventually cured the child completely.

Indian Medical Gazette

OCTOBER

CINCHONA POLICY

We do not feel that any excuse is needed for raising again a subject that has become a perennial one in these columns, namely, the cinchona policy in India. If any excuse were needed, it is provided in the fact that since our last editorial reference to the subject the results of certain investigations that have a direct bearing on this very important subject have been published.

The most important of these publications was the report of the Malaria Commission of the Health Organization of the League of Nations on the therapeutic efficacy of totaquina, which was issued about a year ago. Some of our readers will perhaps remember that in our April issue last year we expressed great disappointment that the sub-committee whom the Commission had charged with the work of appraising the efficacy of various antimalarial drugs had failed to take advantage of a very excellent opportunity to test the comparative antimalarial potency of totaquina, under the controlled conditions that the malarial treatment of general paralytics has provided, in the mental hospitals where this form of therapy is used. This more recent report of the Health Committee deals with the results of trials with the two varieties of totaquina, on the lines suggested by the sub-committee and with supplies of totaquina provided by them, in a number of malarious countries. The following quotation from the introductory paragraphs of this report summarizes the aims of the committee's investigations and in particular their object in introducing totaquina:—

'There was no suggestion of replacing quinine by totaquina. It was intended, however, that the use of mixtures of alkaloids should enable treatment to be extended to the masses These mixtures are, in fact, less expensive than quinine, for they are obtained either by adjusting the residual products of quinine manufacture to the standard specification by the addition of quinine, or by the extraction of all the alkaloids from the bark of the least expensive species of cinchona, such as *C. robusta* and *C. succirubra*. It is a well-known fact that the rationalization of quinine production has led to the selection of that species of cinchona whose bark has the highest quinine content—*C. ledgeriana*, a very delicate species which only flourishes in areas

satisfying certain special conditions as regards altitude, soil, temperature and moisture. The circumstance that only *C. ledgeriana* is at present employed for the manufacture of quinine gives the producing countries a practical monopoly and thereby influences the prices of quinine.

'The two other species—*C. robusta* and *C. succirubra*—which are much less delicate, can be grown in most tropical countries, for which reason their bark is cheaper. Whilst they contain less quinine, their total alkaloid content may be higher even than that of *C. ledgeriana*. Finally, the manufacture of totaquina with such barks is much more economical than the process of quinine extraction, seeing that the various alkaloids are not separated'.

The results of the trials in different countries have been analysed critically by Dr. William Fletcher and his analysis forms the most important part of the report. As was to be expected there was a considerable degree of disparity in the results obtained, not only in relation to the different samples used but according to the places in which the trials were carried out, so that the analysis presented some difficulties. From the point of view of the analyser the most satisfactory trials were carried out at Kuala Lumpur, because parasite-counting methods were employed and at the same time a control series of patients was treated with quinine; the Nanking series must have been one of the least satisfactory, as in this series for some unexplained reason a very large percentage of the patients vomited and therefore probably absorbed smaller and varying quantities of the drug. Although Lieut.-Col. J. A. Sinton's name appears amongst those to whom samples were sent, no report appears to have been received from India in sufficient time to be included in this analysis.

The final opinion of Dr. Fletcher is summarized in the following two paragraphs:—

'To sum up, the records of the cases treated at the different centres show clearly that totaquina acts like quinine as a potent remedy in all forms of malaria; but it must be remembered that a field trial of this kind is not a carefully controlled experiment and, when it comes to deciding whether totaquina is a little better than quinine or not quite so good, one is on less sure ground and, in the absence of adequate controls treated with quinine, the yard-stick needed for more exact measurements is lacking. Similarly, the observations made at the different centres were not sufficiently precise and unanimous to warrant a final decision on the relative merits of the different samples of totaquina.

'As regards toxicity, the case records contain no cogent evidence that totaquina is more toxic than quinine in the doses given, but it is not easily soluble and should not be given in a fluid mixture'.

Similarly the findings of the Health Committee after examining this report were:—

'That totaquina seems able to fulfil the purpose for which it was intended, since, having regard to its efficacy—equal to or only slightly less than that of quinine—, facility of preparation, and cost price, its use would enable malaria treatment to be extended over a wider field'.

Use under normal conditions in a malarious country must be the final test for appraising the value of any antimalarial drug and we therefore fully appreciate the importance of this report. Nevertheless it has had the effect of accentuating our regret, already expressed, that the 'carefully controlled experiments' to decide 'whether totaquina is a little better than quinine or not quite so good', to which this field trial would have formed a most excellent corollary, were in fact never carried out.

The second of the publications to which reference was made above appeared in the March number of the *Records of the Malaria Survey of India*; in this paper the results of a trial with the two types of totaquina and with quinine are reported by Dr. Hicks and Sub-Assistant Surgeon Subedar Diwan Chand, both of the Malaria Survey of India. The trial was carried out on the lines suggested by the Health Committee and the report is a model of what a report of this kind should be. (Elsewhere in this number we have given an extensive extract from this paper.) This trial includes a small untreated series; the fact that the mean duration of fever was not 'significantly' less in this series than in the treated series need shake no one's faith in the efficacy of the cinchona alkaloids, as the series was a small one and certain circumstances made the statistical evaluation of the figures difficult. Judged according to four different criteria of efficacy, namely, the rate at which they banish the parasites from the peripheral blood and the rate of control of the fever, each in benign and malignant tertian malaria, quinine scores one point, totaquina type I one point, and totaquina type II two points. If 'significance' is taken into consideration, and of course it must be, only one point is scored and that is by totaquina type II. There were more than 250 patients included in this trial, and if the 'untreated' control group is excluded, there was an average of 40 patients in each group and no group contained less than 31, so that in point of numbers it may be considered an important series. The results provide unequivocal proof that neither type of totaquina is in any way inferior to quinine in the treatment of either benign or malignant tertian malaria.

The third of these important publications is of interest for a slightly different reason; it is a paper entitled 'Philippine Totaquina', by Drs. Maranon, Perez, and Paul F. Russell, which appeared in the March (1935) number of

the *Philippine Journal of Science* (only received by us in mid-August). By the co-operation of various state departments, Dr. Russell and his co-workers have on a small scale carried out an examination of the problem of the treatment of malaria in the Philippines, from the economic, the botanical, the chemical, and the medical points of view, in the way that for years we have urged in these columns that this same problem as it applies in India should be examined on a scale commensurate with the size of the country and the importance of the problem. The state of affairs in the two countries have many points of similarity; e.g., the real requirements in cinchona alkaloids are at least ten times the actual consumption at the present time; quinine is retailed at an exorbitant price, far beyond that which the peasant sufferer can afford to pay; even the wholesale price is far too high to allow any extensive treatment campaign to be carried out by the government; finally, it is believed by the writers of this paper that a cheap efficient drug could be produced in the country itself which would enable this disparity between the amount of antimalarial drug needed and the amount actually used to be reduced very considerably, just as we believe that if a definite policy were adopted in India this country could be made independent of outside supplies within a very few years. Here the similarity between the cases in the two countries ends, for the idea of planting cinchona in the Philippines only seems to have been conceived within the last decade, whereas the first attempts were made in India almost a hundred years ago, practically synchronously with those in Java which country now holds a virtual world monopoly of quinine.

Though these first attempts were not successful, it is now more than 75 years since cinchona bark was grown in this country on a commercial scale, and to quote from Dr. Russell's paper, 'by 1866 there were more than 1,500,000 plants growing in the Nilgiri Hills, in south-west India, and this number had nearly doubled by 1872'. In the Philippines the first successful attempt was made in 1927, and yet in the treatment experiments reported in this paper the totaquina was prepared from bark produced in the Philippine plantations, where there are already about forty thousand trees growing. The cost of the locally-prepared totaquina has been worked out very carefully and has been found to be only two-fifths of the wholesale price of imported quinine; it is pointed out that if it were prepared on a larger scale a considerable reduction in the cost of production could be effected.

On the clinical trials reported in this paper no great emphasis need be laid; they have shown, just as all other trials have shown, that, given in the doses in which quinine is usually given, totaquina is an efficient anti-malarial drug. The final conclusions at which

these writers arrive are, we think, worth quoting in full :—

'It is not improbable that if every case of malaria occurring in one year in the Philippines could be given a 250-grain treatment there would be needed—at least 30,000 kilograms more specific febrifuge than is now imported.

A 250-grain treatment with quinine sulphate in the provinces costs from 2.50 to 5 pesos (1.25 to 2.50 dollars United States currency). The greater the need, the higher the price. Quinine dihydrochloride retails for from two to four times as much as the sulphate. These retail prices are far more than the average farmer in the provinces can pay. Quinine and the synthetic drugs plasmochin and atabrine may therefore be called a rich man's remedies. There is no probability that much more quinine can be paid for than is now imported.

The Bureau of Forestry has demonstrated that cinchona will grow in the Philippines and will give as good a yield of alkaloids as that grown elsewhere.

From our studies we conclude that the standardized total-alkaloid-extract of cinchona, recommended by the Health Organization of the League of Nations and called 'totaquina', can be prepared locally from Philippine cinchona easily and inexpensively.

We conclude from some clinical tests that this Philippine totaquina is probably about equal to quinine sulphate in its therapeutic value against malaria.

We conclude that, allowing a fair profit to the grower of cinchona, the manufacturer of totaquina, and to the retailer, this Philippine totaquina could be sold to the people at not more than 35 centavos (0.175 dollar) per 250-grain treatment.

Contrasting 35 centavos with the present retail price of from 2.50 to 5 pesos for a 250-grain treatment with quinine sulphate or atabrine, we conclude that the local production of totaquina would materially aid in combating malaria in the Philippines.

We also conclude that the growing of cinchona and the manufacture of totaquina might have considerable economic importance to the Islands, being capable of becoming sizeable new industries'.

This is the position in the Philippines seven years after the cultivation of cinchona was first taken up; one wonders whether these islands will achieve their independence from foreign supplies before we in India with our seventy years' start do. We are afraid we know the answer.

India has never lacked champions of the total-alkaloids cause, but opposition on the one side and lethargy on the other have always proved too strong for them. Only recently, Colonel Chopra, in his drugs enquiry report, presented a strong case for the adoption of some definite cinchona policy, but so far no action has been taken; active opposition is certainly declining, but the lethargy still remains.

The fact that the alkaloids of cinchona other than quinine are of value in the treatment of malaria has been appreciated in this country for the full seventy years since the birth of the local cinchona industry and probably nowhere in the world have alkaloidal mixtures been used so extensively, and yet no policy constructive enough even to lead to the standardization of these alkaloidal mixtures has ever been adopted, and a state of affairs has been allowed to come about where in some provinces the reputation of cinchona febrifuge has sunk to the level of that

of its poorest representative, the hard insoluble cake, consisting of the residual alkaloids, mainly amorphous, and containing scarcely a trace of quinine, that has from time to time found its way into government dispensaries.

Now the League Health Committee have stepped in and suggested a standard, and it seems to us that it would save a great deal of confusion if this standard could be universally adopted. But of course this is not sufficient reason for adopting it unless at the same time it is found to be a satisfactory standard from our (Indian) point of view; on the other hand we should not adopt the attitude that it was not our standard, that we are not going to be dictated to by a lot of foreigners, and that therefore we won't have anything to do with it!

The standards laid down for totaquina must be considered on their merits. As far as we know, no reasonable objection to these standards has been raised. One criticism was that totaquina is a little more expensive to produce *under present conditions* than the unstandardized cinchona febrifuge that is being produced in the Indian factories; we have no doubt that this is the case (just as it would cost the Rolls-Royce Company more to make a Ford car in their factory than it would to make a Rolls-Royce), but we are not interested so much in the cost under present conditions as under conditions that could be brought about by a change of policy in the cinchona plantations and factories in India. The only important point is, can totaquina be made from the total alkaloids of the hardy species of cinchona, *C. succirubra* or the hybrid, *C. robusta*, without subjecting the alkaloidal mixtures to the expensive processes of separation and reblending? From the information available on the alkaloid content of these barks, we gather that it can, but of course this is a point on which an authoritative opinion from the officers in charge of the plantations and factories is necessary.

It is a matter of considerable interest to study the source of and reasons for the opposition to totaquina. In the first place there is serious opposition from the quinine monopolists. From this quarter, together with much praise for quinine and criticism of its rivals, one hears, successively, that the hoards of residual alkaloids (from which type II totaquina can be prepared) are non-existent, that in any case they will be soon exhausted, and finally that quinine manufacturers will be only too pleased to dispose of them, and would encourage their sale if they felt that it was for the benefit of suffering humanity. One must remember that, even if they gained a slight temporary advantage by selling their waste products, the movement for the introduction of totaquina is definitely against the interests of the Dutch monopolists, as their monopoly is dependent on the fact that Java has the most suitable climate

in the world for the production of *C. ledgeriana*, the species which gives the highest yield of quinine, and that, if the demand is for total alkaloids, countries where the hardier species grow well will be able to compete on an equal footing. Opposition from this quarter may therefore be expected, and should be discounted.

Quinine appears to possess an almost uncanny hold on its adherents; to some medical men, otherwise reasonable enough, any suggestion that there may be something as good as, if not better than, the pure alkaloid quinine is sacrilege and arouses within them a vicarious religious fervour. Though one may explain to them that in this instance no attempt is being made to displace quinine and that raising the status of the other members of the cinchona family can only reflect more glory on its most important member, they are still suspicious.

There is the opposition of the passive-resistant type. The representatives of this type know full well the therapeutic value of the mixed alkaloids, and that by introducing them into all government dispensaries much larger supplies of antimalarial drugs could be purchased, and consequently a much larger number of patients treated, with the expenditure of the same money, but they excuse their inaction by cryptic remarks about 'wider issues being involved' and 'the dangers of medical men attempting to interfere in matters beyond their scope'. They also point out that the problem of distribution to the masses is a much more serious one and ought to be tackled first. But surely it is all part and parcel of the same problem; the high price of quinine is the greatest obstacle to its wide distribution to the people, whichever way you look at it; it limits the amount that governments can afford to buy, it encourages dishonesty in dispensers and other distributors, and it complicates the free distribution as the recipients realize that quinine is a valuable saleable article.

Then there are the students of the laws of supply and demand who take the view that as the demand for the mixed alkaloids increases either their price will rise to the present price of quinine, or quinine's will drop to such a low figure that the working of the new suggested plantations will become unprofitable. The first eventuality might conceivably come about, though even in these circumstances it seems improbable, if we increased the consumption of total alkaloid mixtures without changing the plantation policy, but the whole point of our argument is that this policy *should* be changed and the hardier cinchona species planted over a wide area, and in these circumstances we should soon be independent of the world price of totaquina; the second, namely, that our policy in this country will benefit the whole malaria-suffering world by bringing down the price of quinine to a fraction of its present price, is surely too good to hope for; were such

a thing possible (but we see no reason to suppose that it is, as there are many areas in India eminently suited to the growth of high-total-alkaloid-yielding cinchona plants and it should be possible to produce totaquina at a very low cost) then it would be the duty—and not an unpleasant duty as it would be a profitable one—of the government to protect their own industry by imposing an import duty on cinchona alkaloids and other antimalarial drugs.

Finally, there are those who take up the attitude that the present cinchona febrifuge, made in the government cinchona factories, is good enough. They may well be right, but no body of medical men is going to recommend the extensive adoption of a drug of unspecified and varying composition for the treatment of a serious disease like malaria. Sir John Megaw, the late Director-General, Indian Medical Service, though he fully appreciated the necessity for a cheap antimalarial drug, always hesitated to advocate cinchona febrifuge, solely, we believe, for this reason.

Surely the ideal is a high one, the inauguration of a policy that will eventually place an efficient form of treatment within the reach of the whole of the malaria-stricken masses in India. We do not imagine that this can be achieved in one year, or two, or even ten, but unless some definite progressive policy (*e.g.*, one in which all the local purchasing governments agree to replace quinine by totaquina in their hospitals, dispensaries, and rural antimalarial schemes, and at the same time the producing ones agree to extend their plantations of the hardier varieties of cinchona) is adopted it will never come about at all. It will certainly never come about if we are to remain dependent for our supplies of antimalarial drugs from foreign countries, and to allow ourselves to be exploited by foreign monopolists.

Apparently, there are few places in India where the high-quinine-producing cinchona species will grow, therefore there would be serious difficulties in producing sufficient quinine for the country's real requirements, but it would be possible by extending the present plantations to produce in a few years' time enough totaquina to treat India's estimated 100,000,000 sufferers from malaria. (At present only one-tenth of these are treated and two-thirds of our cinchona supplies come from outside the country.) Admittedly, the distribution presents very considerable difficulties but this problem is being tackled in a number of provinces, and here, as we have already said, the high value, as well as the high price, of quinine is a serious obstacle; the difficulties of distribution will gradually be overcome, then the problem of shortage of supplies will become acute unless some policy is adopted in the meanwhile.

We are repeatedly reminded by our opponents of the passive-resistant class that 'wider

issues are involved' and that there is also an agricultural and an economic side to be considered. This we fully realize, but these experts are not going to start their considerations unless we give them the lead.

When writing on this subject before we complained that the medical profession were not in

a position to give a definite answer to the question, 'Is totaquina as good, or nearly as good, as quinine, for the oral treatment of the ordinary attack of malaria?' We are now in a position to say quite definitely that for all practical purposes totaquina is quite as good as quinine. What is to be the next step?

Special Article

THE DYSPEPSIAS OF SOUTHERN INDIA*

By IAN M. ORR, M.D., F.R.C.S. (Edin.)

London Mission Hospital, Neyyoor, Travancore

Of all the conditions which we as medical men are called on to deal with, nothing is more common than dyspepsia in one of its manifold forms. Few diseases are so resistant to treatment, so persistent in their symptoms, and cause so much chronic invalidism as do the dyspepsias. When dyspeptics come to our consulting rooms and outpatient departments we at once look for signs of duodenal ulcer and, failing to find definite evidence of that, we prescribe an alkaline mixture, which nearly always gives some measure of temporary comfort to the sufferer, but leaves the disease unlocated, undiagnosed, and untreated.

I do not wish to dwell at length on the familiar subject of duodenal and gastric ulcer, except in so far as the pathology is peculiar in south India. Nor do I wish to deal with the cause of acute abdominal pain, but rather I would call your attention to the interesting and varied list of conditions that give rise to symptoms somewhat similar, characterized mainly by pain, indigestion and flatulence, and whose pathology nevertheless is so varied.

Stomach

'All is not gold that glitters' and all who have hunger pain, vomiting, and epigastric tenderness, are not necessarily suffering from gastric or duodenal ulcer.

Chronic gastritis.—This is the first and most common condition to which I would draw your attention.

Pathology.—The lining of the stomach becomes coated with mucus which blocks the mouth of the secreting glands. The deeper layer becomes infiltrated with round cells and in an extreme degree the cells of the glands undergo cloudy swelling and may atrophy.

The rugæ of the stomach become larger, firmer and more tortuous; this may be demonstrated by x-ray, by giving a small meal of barium and water only, and pressing the walls of the stomach together, so that the barium just

fills the pockets between the rugæ. The body of the stomach as a whole may be affected and thus the acid-secreting glands which are situated mainly in the body are seriously interfered with, with a resulting fall in free hydrochloric acid, or only the pyloric portion of the stomach may be affected and the hydrochloric acid in the stomach remain normal or high, i.e., we have a hypoaacid gastritis and an acid gastritis.

Ætiology.—This will be discussed more fully below, but it may be said here that the taking of over-spiced and indigestible food, and irregular habits about meals all tend to exaggerate it. Oral sepsis no doubt plays a part. The exhibition of certain drugs for long periods also predisposes towards it; e.g., sodium salicylate, quinine, arsenic, silver, mercury and copaiba. An atrophic form may be found in association with malignant disease; in fact it may be said that malignant disease of the stomach is always associated with atrophic gastritis and malignant disease of other organs, such as the colon, breast, etc., and they usually give rise to it by the absorption of toxins from the disintegrating tumour.

Symptoms.—Discomfort and sensation of fullness which may amount to pain about one hour after food. Appetite is diminished, and there is nausea, a bad taste in the mouth, dizziness, regurgitation and flatulence. This is due to the lack of acid allowing decomposition and carbon dioxide formation. Hydrochloric acid is diminished and mucus is found in excess in the fasting juice. If the pyloric portion of the stomach is alone affected the hydrochloric acid may be high.

Treatment.—Remove all bad teeth, septic tonsils, and deal with sinus infection if any. Lavage with hydrogen peroxide, an ounce to the pint of water, serves to remove the mucus and allows the gastric juice to be secreted freely. This may be repeated daily for a week or until the mucus disappears. If there is hypoaacid, give hydrochloric acid in water with meals. A general tonic containing iron, arsenic and strychnine may be given, but if not well tolerated by the stomach it may be injected in ampoule form.

Diet.—Avoid hot curries, spices, raw fruit, shell fish. Take milk, barley water, congee water, wheat, junket, chicken soup, Horlick's

*Paper read to the Travancore and Tinnevely Medical Association on 10th March, 1935.

milk; later, go on to toasted bread and butter, boiled eggs, white fish, rice.

Mention may be made of atrophic gastritis in contradistinction to the above hypertrophic type. This is chiefly associated with the more severe anæmias and chronic venous congestion. In certain inborn errors also, hydrochloric acid may be absent. The most useful method of determining whether or not an absence of free hydrochloric acid is merely due to mucus blocking the ducts or to an inborn error is to inject 0.5 c.cm. of histamine*, and immediately hydrochloric acid will be poured out in simple gastritis.

Nervous disorders of the stomach.—The nervous system and, particularly, the mental states of fear, worry, excitement, nervous exhaustion, etc., have a marked influence over the stomach. We have all experienced the pre-examination feeling of not wanting a big meal, because of a complete failure of our stomach to secrete its daily quota of free hydrochloric acid. Or the feeling of heaviness in the pit of our stomach when we are disappointed, ill at ease, or distressed. Now let us examine these nervous upsets of the stomach.

(a) *Hyperchlorhydria.*—A point in physiology is important to understand. Stimulation of the vagus causes constriction of the sphincters and outflow of gastric juice. This stimulation of the vagus may be reflexed from gall stones or appendix. There is a lymphatic path from the appendix to the duodenum and it has been demonstrated that chronic inflammation of the appendix causes a spasm of the pylorus and an increase in free hydrochloric acid, a condition favourable to the formation of gastric ulcer.

A state of chronic nerve strain, such as is common to men dealing in big business, is associated with hyperchlorhydria. Excessive indulgence in pickles, spices and smoking have a similar effect. My experience is that the normal acidity curve for the people of south India is higher than for Europeans because of the excessive stimulation of the mucosa by hot curry stuffs.

Symptoms.—These are sensation of fullness and discomfort in the epigastrium and belching. There may be epigastric tenderness. The test meal reveals high acidity and yet the x-ray shows no positive evidence of ulcer.

Treatment consists in avoiding the anxiety state if possible. Avoid carbohydrates, especially rice, and take boiled meat, milk, albumin water, fish and green vegetables. Oily substances have the effect of reducing the outflow of gastric juice and relaxing the sphincter. Hence olive oil, butter and cream should be taken.

*The usual dose of histamine is 0.0005 gramme, so that the author is presumably referring to a solution containing 1 mgm to the cubic centimetre.—EDITOR, I. M. G.

A mixture containing magnesium and bismuth to neutralize the acidity and belladonna to inhibit secretion and relax the sphincter is indicated. Sodium bicarbonate is not deserving of the popularity it enjoys, for, though it does neutralize the acid at first, it then irritates the gastric mucous membrane, causing more acid, and the formation of carbon dioxide and belching.

(b) *Gastro-succorrhœa* (i.e., excessive secretion but not a hyperacid one).

It is common in students at examination times, in girls at puberty, etc. It is characterized by nausea, belching and vomiting of large quantities, for no particular reason. In bad cases the patient may be cold with a slow pulse and sometimes headache due to stimulation of the vagus.

This condition has to be differentiated from:—

- acute gastritis—vomited material alkaline;
- migraine—headache worse and vomitus bilious;
- alcoholic gastritis—occurs in early morning after drinking, bout and vomitus is mainly mucus.

Treatment.—Gastric lavage 1-2,000 silver nitrate to promote mucus formation. Belladonna should be given internally.

(c) *Hypochlorhydria.*—This is found in people suffering from nervous breakdown or extreme nervous exhaustion; also in states of fear. It may be an inborn error, or it may be associated with one of the severe anæmias.

Symptoms.—Loss of appetite, sense of fullness, distaste for meat and there may be diarrhœa, the desire to go to stool occurring immediately after taking food; this is a reflex action and is a common cause of chronic diarrhœa.

Treatment.—Give a diet rich in carbohydrate and condiments, and poor in protein, the reverse of the hyperchlorhydria diet. Give an acid mixture with *nux vomica* and *pepsin*.

(d) *Gastric hyperæsthesia.*—This is found in neurotic people who complain of unusual sensations in the region of the epigastrium and belching, and describe their symptoms with a wealth of detail which is apt to weary the physician. There is usually a completely normal test meal and x-ray, but still the patient complains of pain and tenderness and many other things, and may vomit without relief. This is a pure neurosis and must be treated by removing the patient from the environment of sympathetic friends. Sea bathing, interesting occupation, toning the body by open-air exercise, massage of the abdomen, and rubbing with spirit or camphor. Such a patient will not be satisfied without medicine, and a general tonic containing dilute phosphoric acid, tincture of *nux vomica* and peppermint water will convince him that he is being treated.

One might mention here that belching which is a symptom common to almost all gastric disorders is in most cases due to simple air swallowing and not to

the formation of gas in the stomach. The patient is unaware that he swallows air, and a useful method of getting him to realize the fact and to repress it by an act of will is to tie a string round his neck above the thyroid cartilage and each time he swallows he will notice it and check it. In simple stenosis, however, there is fermentation by yeast in acid medium giving rise to carbon dioxide. In chronic venous congestion also, the vessels of the stomach wall fail to absorb gas which accumulates and is eventually eructated.

Muscular disorders

Gastric atony and dilatation.—*Ætiology.*—

(1) General muscular weakness and enervating surroundings.

(2) Overloading of the stomach, either by living too well, or, in the case of the very poor, by ingesting large quantities of food of poor quality in order to obtain sufficient nourishment.

(3) Sedentary habits.

(4) Auto-intoxication from chronic sepsis.

Symptoms.—These resemble gastritis and hypochlorhydria and indeed may be associated with one or other of these conditions. There is discomfort, feeling of fullness, flatulence, the appetite is good but quickly satisfied. Later on, the tongue becomes broad and flabby, the pulse slow, hands clammy, and there is headache and insomnia. Hydrochloric acid persists for much longer than normal, and organic acids are formed in excess. X-ray reveals a large stomach, no peristalsis, and, while the duodenal cap does not fill of itself, food can be squeezed into it by palpation. There is no tenderness specially related to the duodenum, and no deformity of the duodenal cap, hence duodenal ulcer can be excluded. Also the lack of peristalsis makes an organic stenosis unlikely. The test meal will exclude gastric succorrhœa.

Treatment.—Give dry diet; avoid fat, as it delays emptying and decomposes into fatty acids; avoid bulky diet, like rice, which will increase the condition. Where the patient's means permit, give white fish, chicken, cereals, toasted bread with jam or honey. Stimulants to the gastric muscle, such as nux vomica, quinine and eserine salicylate, are indicated and a general tonic of iron, arsenic and strychnine by injection if not tolerated by the mouth. Gastric lavage 3 hours after meals, to prevent the retention of decomposing foodstuff, is valuable and, unless there is gastritis, magnesium carbonate is as good a substance as any.

Gastric and duodenal ulcer.—This is one of the commonest diseases of this part of India and because of its frequency and the ease with which it responds to surgical treatment we are rather apt to treat it lightly and pass all our dyspepsias over to the surgeon. It is not a common condition, however, in other parts of India. McCarrison reports that in south India 1.765 in every thousand of the population suffer from duodenal or gastric ulceration, while in Lahore, which is typical of north India, only 0.030 per thousand are found to suffer in this

way. That is, in south India it is nearly 60 times more frequent. If the figures of central and north Travancore were examined, they would be twice or thrice that of south India in general. What is the cause of this remarkable variation? The most suggestive possibility is the diet. A diet typical of north India contains large amounts of wheat, milk, mutton, root vegetables, cabbage, dāl and fruit. The balance of protein, carbohydrate and fat is correct and the vitamin elements are well represented in the milk, wheat and vegetables. Compare that with the diet of the poorer class Travancorean where the staple article is tapioca and rice, both almost entirely carbohydrate and almost totally devoid of vitamin substances. The very small amount of mutton, fish and eggs that they are able to get in no way make up the protein deficiency, and the vegetables readily available, such as brinjal, ladies' finger, cucumber, etc., are very deficient in vegetable protein and lack vitamin A. Coconut is rather better and contains a fair amount of fat, but only a small amount of vitamin A. Thus we are dealing with a population living on a high carbohydrate diet devoid of an adequate amount of vitamin elements, vitamins A and D being particularly short (Orr, 1933).

In the nutritional research laboratories at Coonoor an interesting experiment was carried out. Seventeen rats were fed on a typical Travancore diet and 17 were fed on a typical Madras diet which contains more rice and no tapioca. There was a control group fed on a well-balanced diet typical of the people of north India. The control rats remained healthy, the tapioca-fed rats had a 94 per cent mortality and the rice-fed rats an 82 per cent mortality. Forty-seven per cent of the tapioca-fed, and thirty-five per cent of the rice-fed rats were found to have lesions of the stomach. Those fed on tapioca diet were subject to congestion of the stomach and gastritis and both to epithelial overgrowths and ulceration. Those of the rice diet showed a lesion in the body of the stomach and those on the Travancore diet on the pyloric or 'mucous' portion (McCarrison, 1931 and 1931a). Monkeys were fed on a vitamin-deficient high carbohydrate diet and post mortems were found to show congestion and inflammatory changes in the mucous and submucous coats of the stomach, duodenum and lower ileum and colon, degenerative changes in the glands, loss of lymphoid elements, and invasion of the bowel wall by bacterial organisms. In three out of ten monkeys thus fed, gastric ulcer developed.

There appears to be little doubt then that a high-carbohydrate low-vitamin diet produces a gastritis or duodenitis and renders the mucosa liable to ulcer formation. As to the cause of the ulcer, authorities differ but the consensus of opinion seems to be in favour of the view held by Wilkie (1911) of Edinburgh, who has demonstrated that the first part of the duodenum is supplied by a small branch of the pyloric artery, the supra-duodenal artery. This is an end artery and any thrombus forming in its lumen (which might well result from the duodenitis) would produce a loss of vascularity of that part of the gut with necrosis and ulcer formation. Once the ulcer is formed, the gastric juice, which

is made more highly acid than normal by reason of the carbohydrate and the irritation of the condiments, will prevent it healing and lead to chronic duodenal ulcer.

The symptoms and treatment of duodenal ulcer are so familiar that I need not dwell upon them here except to point out one or two important facts.

(1) We have seen already that many things such as gastritis and hyperchlorhydria may cause pain, vomiting and epigastric tenderness.

(2) Hunger pain which is typical of duodenal ulcer may occur occasionally in cases of gall stones, appendicitis, dyspepsia, and excessive smoking.

(3) A feature of peptic ulcer which is not produced by other conditions is the marked periodicity. That is, in the early stages the pain is only present for a few days and then completely disappears for a long period only to return again. These periods of remission become shorter and shorter, and in the late stages when there is much associated gastritis the patient may say that he has no remission of symptoms. This periodicity corresponds to the healing and breaking down of duodenal ulcers.

(4) The vomiting typical of a peptic ulcer occurs at the height of the pain, it relieves the pain, and is highly acid in its reaction.

(5) The test meal and the x-ray are the final criteria by which we judge whether there is, or is not, a peptic ulcer and I would lay stress upon the use of the fluorescent screen and palpation in the diagnosis. To see the stomach on the screen and mark the point of tenderness, to witness the movements of the stomach and the way in which the duodenal cap fills is of the greatest importance.

Malignant disease of the stomach.—Here again a few words will suffice to call your attention to some important points. Moynihan (1909) propounded the view that 70 per cent of gastric ulcers became malignant and he consequently treated all gastric ulcers as potential cancer. Also he looked for previous ulcer symptom in the diagnosis of cancer. Modern surgical pathologists incline to the view that only 5 per cent of gastric ulcers become malignant and that much of the material Moynihan based his statistics upon were not cancerous ulcers at all, but merely advanced stages of simple ulcers. The point we must note however is that the majority of cancers of the stomach we see will have a short history. Any complaint of dyspepsia with loss of weight and appetite occurring in a man over forty who has never had anything wrong with his stomach before is very suspicious of malignant disease.

Cancer of the stomach will show the following :—

- (1) low or absence of free hydrochloric acid;
- (2) a trace of blood in every specimen of the test meal;

(3) distaste for meat; and

(4) a deformity of the antrum of the stomach in the x-ray.

Never wait to palpate a tumour before diagnosing cancer of the stomach. The signs and symptoms apart from the above are often indefinite and confusing, but it is far better to operate and find no cancer than to wait until secondaries have spread to the glands and liver.

There are certain other conditions that we must consider to make our review complete.

Gall stones and cholecystitis.—The special interest of this condition lies in the fact that it is so very uncommon in this part of the world. In Neyyoor we always examine the gallbladder in our abdominal operations, so that few if any gross pathological changes in this organ have not been seen and dealt with; yet in a series of 2,300 upper abdominal operations, only in 38 has gallbladder pathology been noted, a ratio much smaller than that found in western countries or even in central India. It is well recognized that the formation of gall stones depends on three factors:— (1) increased cholesterin in blood, (2) some impediment to the flow of bile, and (3) some chronic inflammation in the wall of the gallbladder.

Increase in cholesterin is found mainly in pregnancy, hence gallbladder disease is more common in women. It is said to be increased in typhoid fever. It is definitely increased in certain diets and may be reduced by a cholesterin-free diet.

Biliary stasis is probably more associated with people living sedentary lives, and, as the average Indian woman is more a domestic drudge than her European sister and wears clothes which are freer and do not compress the lower thorax, she probably suffers less from biliary stasis.

Infection of the gallbladder is said to occur in typhoid fever. Cushing (1898) found 30 per cent of these gallbladder cases had suffered from typhoid. Another observer, Chiari, found *Bact. typhosus* in the gallbladder of 19 out of 22 persons who had suffered from typhoid. Now surely in a land like this, where typhoid is extremely common, we would expect to find a higher ratio of gallbladder disease. I have no experimental evidence to give you and can only throw out a suggestion which perhaps someone may be able to substantiate or refute. Though the gallbladder mucosa is frequently infected by typhoid, the other two factors necessary for stone formation are absent, namely, (a) increased cholesterin, as the poorer people at any rate live on a cholesterin-free diet and (b) lack of biliary stasis due to the costume and activity of the poorer women. So it is an ill wind that blows nobody any good; the diet that brings us peptic ulcer and gastritis safeguards us from gall stones.

But they do occasionally occur, particularly in the better classes who can afford a richer diet, and it behoves us to be familiar with the symptoms and differential diagnosis.

Symptoms.—Periodicity is absent in contrast to ulcer. There may have been attacks but there is always a continuous discomfort between the attacks. There is usually a history of jaundice, but jaundice may not be present at the time of examination. The patient, usually a stout well-nourished individual, complains of pain in the right hypochondrium, a feeling of fullness relieved by belching, not relieved by lying down and made worse by taking fat or eggs. This is peculiar to gallbladder infection, just as distaste for meat is typical of malignancy and hypochlorhydria. The free hydrochloric acid is low and the total acidity low, which contrasts with peptic ulcer and hyperchlorhydria. Tenderness is most marked over the tip of the 9th costal cartilage and is more marked on taking a deep inspiration.

Only pigment stones and those on which calcium has been deposited are seen by the x-ray but an idea as to the function of the gallbladder can be obtained by cholecystography.

Diseases of the pancreas.—Reference will only be made to two conditions that give rise to chronic abdominal pain and indigestion.

Pancreatic calculi.—This is not common but we have met with three cases recently in Neyyoor. In one, the symptoms were typical and pronounced; they are detailed below.

The patient was a thin man, not like a gallbladder subject; he suffered from repeated attacks of acute colicky pain which radiated to the left and to the left shoulder. He was tender in the epigastrium and had a weak thin rapid pulse. There was no history of jaundice which ought to have given us the clue, for an attack of biliary colic without at least a trace of jaundice must be uncommon. Also the pain did not radiate to the back and right scapular region as is usual in biliary colic, but across the epigastrium and to the left.

One feature of pancreatic calculi which is of diagnostic value is that they contain large quantities of calcium carbonate and are therefore easily seen by the x-ray; they can be removed by operation.

Chronic pancreatitis.—This is of two varieties, interlobular and interacinar. They are apparently similar in aetiology but differ in the effects they cause. The first affects only the cells of external secretion, the interacinar on the other hand is a general fibrosis of the gland and affects the islets of Langerhans, giving rise to glycosuria.

Aetiology.—Infection plays the primary part; it may reach the gland by :—

(1) the pancreatic duct, and is more often associated with acute pancreatitis,

(2) the blood stream in intestinal stasis, and may follow typhoid, or

(3) the lymphatics; there is an intimate connection between the lymphatics of the duodenum and gallbladder, and the pancreas,

and it is undoubtedly by this route that the chronic pancreatitis we see commonly arises.

Symptoms.—It affects middle-aged men and women; there is often a previous history of typhoid. There is a general bodily wasting, indigestion and attacks related to food but which may last over one or two meals. The appetite is poor and vomiting gives no relief. There is tenderness in the epigastrium radiating to the left and into left shoulder.

Stools.—Large and bulky and more oily than normal. Microscopically they show an increase in fat, but they can be distinguished from the fatty stools of gall-stone obstruction in that there is a great increase in unsplit fats. The unsplit fats can be distinguished from the split fats by staining with Nile blue which shows the globules of unsplit fat as bright red spots in a deep blue field. Unaltered meat fibres will be seen also, but there will not be much change in carbohydrate metabolism.

Special tests depend on the power of the pancreatic secretion to digest gelatin. A drug such as iodoform is given in a gelatin-coated capsule. If the pancreatic secretions are working actively the capsule will be digested and iodine will appear in the saliva in four hours. In pancreatic disease however the gelatin-coated capsule will pass unaltered by the pancreatic ferments. The diastase reaction is a very uncertain test and only positive in extreme degrees. At operation the gland is often found to be enlarged and hard.

Treatment.—Depends firstly on dealing with any duodenal or biliary sepsis by surgical measures, but, if no lesion in either of these organs is found, justifying a cholecystectomy or gastro-enterostomy, the correct procedure is to drain the gallbladder. This acts by draining away a possible source of sepsis and also as the pancreatic and common bile duct, in the majority of people, open into the ampulla of Vater it is a means of draining the pancreatic duct (figure 1). I have carried out this in four cases recently with good results.

Fig. 1.—Showing the common bile duct and pancreatic duct opening into ampulla of Vater. Hence drainage of the gallbladder will also indirectly drain the pancreatic duct.

Appendix dyspepsia

This much-maligned organ carries far more than its share of responsibility for surgical intervention, largely because it is so easy to remove a healthy appendix and the mortality is practically nil, while the removal of a gall-bladder is a more formidable procedure. So many unfortunate patients have an innocent appendix skilfully removed and are left to suffer from chronic cholecystitis, salpingitis, or visceroptosis.

Nevertheless apart from acute appendicitis there is a condition known as chronic appendix dyspepsia, and owing to the lymphatic drainage of the appendix and its connection with the duodenum an unhealthy appendix may upset the gastric function to a considerable degree. A few points on the diagnosis of chronic appendix dyspepsia will therefore be in keeping here :—

(1) There will nearly always be a history of one, two or three acute attacks, rarely more.

(2) Each attack tends to be worse than the last and pain remains in the intervals.

(3) There is deep tenderness at McBurney's point.

(4) The acute attacks commence at the umbilicus and spread to the right iliac fossa, and are associated with pyrexia; this is an important distinction from visceroptosis, which we will consider next.

(5) The x-ray may reveal a kinked or fixed appendix, or barium may fail to fill it; all these suggest appendix trouble.

(6) On dilating the colon with air from an enema pump and pressing over the distended sigmoid, pain will be felt in the right iliac fossa in many cases of chronic appendicitis.

Visceroptosis.—This is the next cause of chronic abdominal pain to which I would direct you.

In my earlier years in India I dismissed this subject as one applying mainly to European women and not to be considered in dealing with the Indian dyspeptic, but my attention is being drawn more and more to it. I have repeatedly operated on a spare melancholic young woman suffering from the symptoms of duodenal ulcer only to find that there was no visible palpable ulcer, that the first part of the duodenum could be delivered outside the abdomen unusually easily, and that the cæcum was extremely mobile and had attached to it a very innocent looking appendix. I found that if one removed the appendix the patient was better for a time and then came back again or went to some other surgeon with the same symptoms.

Let us consider the four factors in visceroptosis and see if they throw any light on this type of case :—

(a) abnormal mobility and dilatation of the gastro-intestinal tract,

(b) the presence of accessory bands or membranes,

(c) changes in the body structure, and

(d) altered mentality.

All who have low viscera have not got symptoms and yet all who have symptoms of visceroptosis have low viscera.

The principal organs affected by (a) are :—

(1) the stomach whose greater curvature may droop into the pelvis and the lesser curvature be kinked and U-shaped;

(2) the duodenum which may be more mobile and which is sometimes crossed in its third part by the superior mesenteric artery which will be drawn more tense by the drag of the ptosed intestines and constrict the duodenum causing duodenal ileus (figure 2);

Fig. 2.—Showing ptosis of cæcum causing drag on superior mesenteric artery and kinking of duodenum.

(3) the cæcum may be in the pelvis or more mobile than normal and dilated or may be restricted by unusual bands. The colon also is more mobile and may be kinked at certain points by bands.

(b) The bands are definite in their situation and are known as Jackson's membrane, Lane's kink, Payr's membrane and Toldt's membrane (figure 3). I once came across a case where the transverse colon was kinked into a U, and the two limbs of the U held in apposition by a membrane (figure 3). I treated this case which was suffering from the symptoms of intestinal stasis by colectomy.

(c) The changes in body structure fall into two categories, virginal ptosis and maternal ptosis.

(1) *Virginal.*—The patient is a young woman, with tissues poorly developed, little fat, narrow thorax, loss of lumbar curve, and slightly protruding lower abdomen. These signs are present from childhood but only in adult life do symptoms appear.

(2) *Maternal.*—This occurs in elderly or middle-aged women who have borne children.

The abdomen is broad with wide thorax, loss of lumbar curve and a marked protrusion of the lower abdomen. The signs and symptoms do not appear till after several pregnancies and

Fig. 3.—Showing the sites of bands and kinks.
(1) Jackson's membrane. (2) Payr's membrane.
(3) Toldt's membrane. (4) Lane's kink.

are due to loss of muscular tone often associated with loss of fat (figure 4).

—(d) *Changes in mentality.*—The patient is despondent, inclined to exaggerate her condition and can give off readily a long list of bodily ailments.

Fig. 4.—(1) Normal contour. (2) Virginal ptosis.
(3) Maternal ptosis.

Ætiology.—There are two functions of muscle, one is to produce movement and the other to maintain bodily posture. These two functions are evidently carried out by different parts of the muscle fibre and the postural tone may be lost without the power of movement being lost or diminished. This postural tone has to be

acquired in childhood by an act of will, till it becomes second nature to stand and sit correctly and the will plays no further part. In children of poor mentality brought up in unhygienic surroundings with little or no training, as are so many girls in this country, the will never acts strongly enough to maintain the correct posture and they go into adult life in the ptosis condition. In adult life with the increased strain put upon the body the ptosis becomes worse. Symptoms only appear, however, if there are present some of these congenital bands or membranes which kink the ptosed organ and eventually lead to intestinal stasis and toxic absorption.

The symptoms are very varied but are all characterized by the fact that no matter what the nature of the pain, it is worse at the end of the day and is relieved by lying down. The patient has a typical bodily structure and feeble mental outlook, and while the patient is usually a woman men are sometimes affected. The symptoms may simulate the following diseases:—

(1) *Chronic appendicitis*, but instead of two or three attacks there may be a history of numerous attacks, not getting worse as does appendix dyspepsia. Vomiting is repeated and not just at the commencement of the attacks. Pyrexia is absent and there is no hyperæsthesia over Poupart's ligament, but an area of hyperæsthesia to the right of the umbilicus. The cæcum is dilated, splashing can be elicited and there is frequently a ptosis of the right kidney. This picture was implanted on my mind by a young unmarried woman who had had her appendix removed by another surgeon and came complaining of the usual pain in the right iliac fossa. Suspecting some adhesions or pelvic trouble I operated again and removed a large fibroid from the uterus. She was better for a time and then came again complaining of pain which was made worse after walking about but did not trouble her when resting. Careful palpation revealed a mobile right kidney and the x-ray revealed a general ptosis of the cæcum. As she was well off I had a visceroptosis belt made for her which gave her great comfort and relief.

(2) *Peptic ulcer* may also be simulated, but there will be no periodicity and no freedom between attacks, and pain commencing after a meal has not completely disappeared before the next meal. The patient is relieved by lying down. There is loss of desire for food, but no real fear of taking food. X-ray is typical and there may be local spasm suggesting ulcer. I have operated on many of these cases expecting to find an ulcer and instead have been confronted only by a duodenum which was easy to deliver and a spasm of the pylorus which might easily deceive one into thinking an ulcer existed. More careful pre-operative x-ray examination can exclude ulcer and the general

build of the patient ought to be a guide. Duodenal ileus to which I have already referred can also be readily diagnosed by the x-ray by noting a fullness of the second and third parts of the duodenum.

Cholecystitis and cancer of the stomach may also be simulated, but x-ray and response to rest and lying down, and the typical figure must be our guide.

Treatment of visceroptosis.—We must remember in treating this disease that there is no short cut, no easily-performed operation which will relieve the condition for we are dealing with people who have faulty postural tone, faulty habits, membranes and bands, as well as ptosis or a poor mentality which makes them unable to co-operate.

As the trouble in the virginal type starts in childhood, more careful training in school and by parents would prevent a lot of it. Until girls are treated with greater frankness and given more freedom it is unlikely that the mental problems will be solved.

In the established disease we must deal first with the poor tone and faulty posture. The first thing is rest in bed and during that time the muscles should be developed by massage and gentle exercise of gradually increasing severity. Deep-breathing exercises to develop the thorax and restore the lumbar curve must be carried out. A diet calculated to increase the amount of fat must be given if the patient's

means permit, and regular bowel movement by means of liquid paraffin is desirable. When the patient's circumstances make prolonged rest impossible a properly fitting abdominal belt often gives relief, but massage and exercise must be carried out as well.

The surgical treatment is unsatisfactory, but a mobile cæcum may be fixed by a cæcoplexy operation, and a ptosed stomach can be hitched up by means of one of the various methods of shortening the mesentery. The bands causing kinking may be divided and duodenal ileus may be relieved by a gastro-enterostomy, or duodeno-jejunoscopy, but it must be remembered that such operations will not relieve a general visceroptosis nor will they of themselves bring relief unless combined with rest, massage and exercise as described already. If the patient is neurasthenic never operate; it only makes matters worse.

Medical News

INTERNATIONAL CONGRESS ON HEPATIC INSUFFICIENCY

An international congress on hepatic insufficiency will take place at Vichy in 1937, under the presidency of Professor Loeper, member of the academy of medicine.

The congress will be divided into two sections: Medicine and Biology, and Medical and Surgical Hydrotherapy.

This scientific meeting is a sequel to the congress on biliary lithiasis in 1932, which was presided over by Professor Carnot.

INTERNATIONAL UNION AGAINST TUBERCULOSIS

The executive committee and the council of the International Union against Tuberculosis, whose secretary-general is Professor Fernand Bezancon, met in Paris, at the Headquarters of the Union, 66, Boulevard St. Michel, on the 10th and 11th July, 1935, under the chairmanship of Dr. Piestrzynski, Under-Secretary of State for Poland. Delegates from 20 countries attended this meeting. The administrative meeting of the council was devoted to the preparation of the programme of the conference of Lisbon which is due to take place on the 8th, 9th and 10th September, 1936. The agenda of this conference is now definitely settled and will include the three following subjects: 'Radiological aspects of the pulmonary hilum and their interpretation', opening report by Professor Lopo de Carvalho (Portugal); 'Primary tuberculous infection in the adolescent and the adult', opening report by

Dr. Olaf Scheel (Norway); 'The open case of tuberculosis in relation to family and domestic associates', opening report by Sir Henry Gauvain (Great Britain).

At the scientific meeting of the council Professor Lyle Cummins (Cardiff) occupied the chair. Professor Madsen, of Copenhagen, submitted a report on 'Tuberculin standardization and tuberculin tests'. Dr. Kendall Emerson, Managing Director of the National Tuberculosis Association, gave an account of the work of Dr. Long and his collaborators who claim to have isolated the active principle of tuberculin. In a discussion in which Professor Madsen, Professor Lyle Cummins, M. Boquet, Professor F. Bezancon, Professor Sergeant, Professor Debre, Dr. Lesne, Dr. Rist, Dr. Troisier, Dr. Saenz, etc., took part, the respective merits of Pirquet's cuti-reaction and Mantoux's intradermal test were compared. The majority of the French speakers expressed a preference for the former method while their colleagues from other countries spoke on behalf of Mantoux's test. They all agreed on the advisability of adopting a standard tuberculin and a uniform tuberculin test.

COURSE OF INSTRUCTION IN MALARIOLOGY UNDER THE AUSPICES OF THE EASTERN BUREAU OF THE LEAGUE OF NATIONS, SINGAPORE

The Health Committee of the League of Nations is arranging for a third course of instruction in malariology which will commence at the King Edward VII College of Medicine at Singapore on 27th April, 1936.

It will be preceded by a preliminary revision course lasting four days for candidates with a limited experience of the subject. The theoretical and laboratory studies will continue until the end of May, after which the candidates will proceed in groups to Malaya, to Java or to French Indo-China for a further period of practical field work extending over three weeks. The object of the course is to complete the training of medical practitioners who are engaged, or intend to be engaged, in the work of malaria control in their own countries. The courses will thus be of interest not only to governments and municipal authorities but also to all medical men practising in eastern countries, particularly those engaged in estate work.

The administrative duties will be carried out by the Eastern Bureau.

There will be three distinct stages to each course:

- (1) A preliminary revision course;
- (2) Theoretical and laboratory studies with practical demonstrations;
- (3) Practical field studies.

The preliminary revision course is designed for students who have a limited practical experience of malaria, and those who may wish to revise the principles of hæmatology, protozoology and entomology, and the clinical aspects of malaria. It was introduced to avoid the inclusion of the more elementary aspects of these subjects into the main course, which were not required by the more experienced students. The preliminary course occupies four days, beginning at 8-30 a.m. on Wednesday, 22nd April, 1936.

The theoretical and laboratory studies of the main course will commence at the King Edward VII College of Medicine at 8-30 a.m. on Monday, 27th April, 1936, and will be completed on the 30th May, 1936.

The practical field studies will commence at the beginning of June, and for this the candidates will be divided into groups, one of which will study in Malaya, one in French Indo-China, and probably another in

Java. They will last approximately 21 days, during which the student will have the opportunity of becoming familiar with the routine of a malarialogist and the actual application of anti-larval and other anti-malarial measures to field conditions.

The League of Nations is making available a limited number of partial fellowships to candidates who are nominated by their Governments, on condition that these Governments bear half the cost entailed by their nominees.

Conditions of admission:

The subscription for the theoretical and laboratory course will be 75 Straits dollars, and will be received by the Eastern Bureau of the League of Nations at Singapore.

Candidates not attending the preliminary course will be expected to possess a working knowledge of malaria and of the fundamental principles of the contributory subjects, such as hæmatology, protozoology and entomology.

Any further information desired will be supplied by the Director of the Eastern Bureau of the League of Nations, 336, River Valley Road, Singapore, to whom applications for admission to the course should be addressed. These should reach Singapore not later than the 29th February, 1936, and as only thirty candidates can be admitted, early application is desirable.

INDIAN MEDICAL COUNCIL

MAJOR-GENERAL SIR F. P. CONNOR, *Kt.*, D.S.O., F.R.C.S., D.T.M. & H. (Eng.), L.R.C.P. (Lond.), R.N.S., I.M.S., Surgeon-General, Madras, has been duly nominated by the Government of Madras under Clause (a) of subsection (i) of Section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India, *vice* Lieutenant-Colonel R. E. Wright, C.I.E., I.M.S., resigned.

Current Topics

The Relative Clinical Efficacy of Totaquina and Quinine

By E. P. HICKS, M.D., D.T.M. & H.

and

SUBEDAR DIWAN CHAND, I.M.D.

(From the *Records of the Malaria Survey of India*, Vol. V, No. 1, March 1935, p. 39)

TOTAQUINA is a mixture of cinchona alkaloids prepared according to the formula of the Malaria Commission of the League of Nations (1934). It must contain at least 70 per cent of crystallizable alkaloids and 15 per cent of the total weight must be quinine; not more than 20 per cent may be amorphous alkaloid. It has been introduced as the result of a search for a drug suitable for the treatment of the vast malarious populations of the world which are too poor to buy quinine. As such, it must approach quinine in efficiency and safety, while being considerably lower in cost.

The formula allows for the preparation of totaquina in two ways. Type I is prepared by the precipitation of all the alkaloids of cinchona bark; type II is obtained from the alkaloids left after the removal of quinine, by adding to the residue enough quinine to bring the final mixture up to standard. It is intended that type I shall be prepared from trees such as *Cinchona succirubra* and *robusta*, which can be grown with comparative ease in many parts of the world, and which give a satisfactory yield of total alkaloids. Type II

is suitable for production from *C. ledgeriana*. This species is richer in quinine, and therefore more profitable commercially, but has a more restricted area of growth. It is expected that totaquina will be cheaper than quinine because all the alkaloids of the bark are used, and because it can be prepared from trees which will grow in many countries, thus evading the present restriction.

The Malaria Commission of the League of Nations, in making arrangements for trials of totaquina in many parts of the world, laid down the experimental method which is considered desirable. We have endeavoured to adhere to these recommendations as closely as local conditions allowed, in order that our results might be comparable with those of workers in other countries.

Experimental method recommended by the Malaria Commission of the League of Nations

The drugs are to be judged by their immediate therapeutic efficacy when given to patients who are in hospital and whose blood contains parasites at the time of treatment.

(a) Give each drug in tablet form by the mouth under medical supervision; the dose for 70 kg. of body-weight to be of 0.6 gm. for benign tertian; and 1.2 gm. for malignant tertian or quartan.

(b) Treat only those who have asexual parasites circulating in the blood. Give one dose daily, and make a blood film at the same time.

(c) Give the drug and make blood films for five days.

(d) Record toxic symptoms.

(c) The criterion will be the time required for the disappearance of asexual forms. The blood examinations should be carried out by the same technique and the same observer throughout, by counting one hundred fields of a thin film (*frottis*).

(f) The experiment should be made on groups of fifty patients for each drug, without preliminary selection of the patients.

(g)

(h) It is desirable to state whether the case is a first attack, a relapse or a reinfection, and previous treatment should be recorded.

Type of population under observation

The patients described in this report were male prisoners at the Central Jail and the Borstal Institution of Lahore. At the Borstal Institution, only those patients are included who were sixteen years of age or older, so that their degree of immunity is approximately the same as that of the adults in the Central Jail. The average weight of prisoners was 121.5 pounds; 84.5 per cent of the weights fell between 100 and 139 pounds. Work at the Central Jail was carried on from 17th May to 5th December, and at the Borstal Institution from 6th June to 8th September, 1934.

These men have been exposed to both endemic and periodical epidemic malaria all their lives. It is unlikely that any of our patients was suffering from his first attack, but a distinction between relapses and reinfections could not be made.

The patients were seen by us as soon as they complained of fever to the Jail Medical Officer. Many of them asserted that they had already suffered from fever for several days before reporting to hospital; this may in part account for the rapid response of the infections to cinchona alkaloids. They received no prophylactic quinine, and every effort was made to ensure that they obtained no antimalarial drug before they were sent to us. We believe that if any of our patients did receive such drugs, it was a very rare occurrence. To confirm this, the urines of a number of new patients, who had not yet been given cinchona alkaloids by us, were tested by Tanret's reagent. The reaction for quinine was given only by one man, who was not diagnosed as a case of malaria. When the patients left our ward, however, the treatment was completed by a short course of quinine.

Technique

The blood of all men complaining of fever was examined by thick and thin films. When a diagnosis of malaria was made, the patient was given two grains of calomel, a second thick film of his blood was made, and the parasites were counted by the fowl-cell method. He was then given the appropriate specific drug in tablet form in the prescribed dosage. Quinine sulphate and totaquina, types I and II, were given to alternate cases of benign tertian, and similarly to alternate cases of malignant tertian malaria. The patient was examined clinically for signs of intercurrent disease. Temperatures were taken at about 8 a.m. and 5 p.m. A magnesium sulphate mixture was given every morning to all men under treatment, and calomel was repeated when necessary. No other drug was taken.

Every morning the parasites in the patient's blood were counted, and a dose of the specific drug was given shortly afterwards. One dose only was administered each day. This continued until the blood was free from parasites for at least two consecutive days, and there had occurred at least one day free from fever, which was not followed by a subsequent recurrence of fever.

In endeavouring to estimate the frequency of toxic symptoms we avoided leading questions, merely putting to each man the daily question, 'How do you feel?' and recording his answer.

The quinine and both types of totaquina were provided by the Madras Government Cinchona

Department. The composition, as given by them, is shown below:—

	TYPE I	TYPE II
	Per cent	Per cent
Quinine ..	32	19
Quinidine ..	1	4
Cinchonine ..	11	20
Cinchonidine ..	30	26
Amorphous alkaloid ..	15	19

The total crystallizable alkaloids in type I are 74 per cent of the mixture, and in type II are 69 per cent. This corresponds roughly to the amount of alkaloid in quinine sulphate, which is 73.5 per cent. The tablets were of moderate size, each containing 0.25 gm. of the alkaloids. A dose consisted of one or more whole tablets, together with one tablet which was cut down to a size estimated to complete the correct total dose. This method is rather rough, but on account of the size of the tablets and the small amount of alkaloid in each, we do not think that the error was serious.

It will be seen that the above methods are those proposed by the Malaria Commission of the League of Nations with three exceptions. Firstly, the parasites were counted by the fowl-cell method. Secondly, it was impossible to distinguish between first infections, relapses and reinfections, or to record previous occasions on which the patient had been treated for malaria. Thirdly, the treatment was stopped when the patient had been free from parasites for two days and from fever for at least one day.

Control experiment

All the men probably possessed a considerable degree of immunity to malaria, and recovered quickly under treatment with cinchona alkaloids. It appeared possible that they might have recovered nearly as quickly with simple rest in bed and without specific treatment, a state of affairs which would have vitiated any conclusions drawn from figures claiming to give the results of treatment. Accordingly ten benign tertian cases were taken as controls and were put on a course of a simple diaphoretic mixture without any specific drugs. These alternated with cases taking cinchona alkaloids. In one control case it was necessary to terminate the attack on the second day by giving quinine; this man is not included in the table of results. In another case, totaquina type I was given on the fifth day.

Absorption of quinine and totaquina

The tablets of all three drugs disintegrated easily. When a tablet was placed at the bottom of a test-tube of tap water, it broke up in a few minutes without being shaken.

Every dose of cinchona alkaloids was given personally by one of the authors, who afterwards examined the man's mouth with the aid of a tongue depressor to ensure that it had been swallowed. The men showed no dislike for the tablets.

The administration of calomel and magnesium sulphate was intended to bring the intestines of all patients into a suitable condition for the absorption of the alkaloids.

To confirm the absorption, the urines of a number of cases were tested with Tanret's reagent from one to three hours after the administration of the drug. In all cases they gave the reaction for cinchona alkaloids. In view of these facts it may be assumed that the results of treatment were not influenced by inequalities of absorption.

Results

[The results of treatment are shown in tables which we are not reproducing, but which we have summarized below. Ed., I. M. G.]

In a small control series in which no treatment was given for a period of 5 days to 9 patients with benign tertian infection, the fever in 8 patients subsided within

3 days, so that there was little difference between this series and those treated with cinchona as far as the fever was concerned but the rate of disappearance of the parasites was significantly different, in favour of the cinchona series.

		MEAN DAYS OF DURATION OF FEVER		MEAN DAYS OF PERSISTENCE OF PARASITES	
		B. T.	M. T.	B. T.	M. T.
Quinine	..	1.51	1.98	1.05	1.28
Totaquina I	..	1.67	1.90	1.20	1.27
" II	..	1.42	1.91	1.08	0.99

In the malignant tertian cases the period of disappearance of parasites is 'significantly' lower in the case of the totaquina series than in the others; otherwise there is no significant difference between any two series. The incidence of toxic symptoms is materially the same in all the series.

Discussion of results

The material for the experiment consisted of Indian males who were 16 years of age or older. It is unlikely that any were suffering from their first attacks of malaria, and perhaps many of the benign tertian cases were relapses. Probably all the patients had some degree of immunity, varying with the individual, but the number of cases recorded is large enough to suppress serious errors arising from the individual factor. This also applies to the question of a possible multiplicity of strains of parasite, of which some may have been more amenable to cinchona than others.

The dosage was that recommended by the Malaria Commission of the League of Nations (1934). It was small and calculated to display slight differences in efficacy better than larger doses would have done. Where two drugs differ slightly in their action and are given in massive doses, these slight differences are likely to be masked.

If the criterion of the relative efficacy of quinine and totaquina is taken as the mean time required for the disappearance of parasites and fever, it will be seen that, though on the whole the variations are in favour of totaquina type II, in most cases the differences between the drugs are small and are within the limits of error due to random sampling. According to conventional usage, differences have been considered as 'not significant' when P is greater than 0.05 or the difference of the means is less than twice the standard error of that difference. By this test, the only case which is significant is that in which malignant tertian parasites disappeared more quickly under treatment with totaquina type II than with quinine. Here P is slightly less than 0.05, and the difference is slightly more than twice its standard error. It is possible that totaquina type II is more lethal to *P. falciparum*; but on the other hand there is some evidence that chance distributed milder cases to this drug for, among the patients treated by it, fever was recorded in only 31 (61 per cent), while the figures for quinine are 44 (82 per cent) and for totaquina type I are 42 (79 per cent). It will be seen that totaquina type II was not superior in banishing fever from those malignant tertian cases which suffered from fever.

The contrary seems to have occurred in the results for benign tertian, where totaquina type I has been less successful than either of the other two drugs in destroying parasites. Here the figures for febrile cases are for quinine 41 (59 per cent), for totaquina type I are 48 (70 per cent) and for type II are 36 (50 per cent).

Our conclusion, therefore, is that, under the conditions of this experiment, there was no distinct difference in efficacy between quinine and the two types of

totaquina in clearing the blood of parasites and in subduing fever. As to the relapse rate, we have no data on which to form an opinion.

Discussion of toxic effects

The toxicity of the samples was not easy to estimate. The statements of prisoners about subjective symptoms are not always reliable, as they naturally find it easy to remember those which they hope will ensure a longer stay in hospital. It was noticeable that toxic symptoms occurred in epidemics. When one man complained of vertigo, others in the ward would remember that they had been similarly troubled. At another time the prevailing complaint was 'weakness'.

In view of the unreliability of the complaints on which the records are based, it would be unwise to place much weight on the small differences observed, or to conclude that our figures display any real difference in toxicity between the three drugs. Indeed, it would have been surprising if this small daily dosage had provoked clearly defined toxic symptoms. In this connection it may be noted that Fletcher (League of Nations, 1934), when reviewing the trials of totaquina conducted under the auspices of the League of Nations, concluded 'As regards toxicity, the case records contain no cogent evidence that totaquina is more toxic than quinine in the doses given'.

The above results are in agreement with those which have been obtained in trials in other countries, and have been published by the Health Organization of the League of Nations (1934). The practical application remains to be considered.

Optimum dosage

The experiments give some evidence of the optimum dosage for a population having a degree of immunity comparable to that of our patients. Among all our men, only one had urgent symptoms. This was a case of malignant tertian malaria, who became comatose within an hour of taking his first dose of totaquina type I. It cannot therefore be considered as showing insufficiency of drug or dosage. We suggest that a dose of 1.0 gm. or 15 grains once daily for three or four days would be suitable for the routine treatment of rural populations in the Punjab. This should be large enough to prevent the majority of deaths and to remove clinical symptoms, which is all that is demanded by such populations.

The position of totaquina as an antimalarial drug

A drug which is to be distributed to poor malarious populations must be efficient, safe and cheap. The evidence shows that both types of totaquina are efficient and safe, but the question of price is more difficult. It would be out of place to discuss it at length in this paper, but the following general considerations may be of interest.

The mixture of cinchona alkaloids known as cinchon febrifuge is cheap because it is a by-product of the manufacture of quinine. If totaquina type II is produced by adding quinine to a mixture of residual alkaloids, its price will be higher than that of cinchon febrifuge by the cost of the added quinine and the expenses of analysis. The latter might be a serious addition to the cost if spread over a comparatively small bulk of the drug. Thus, on a small scale, totaquina must be more expensive than cinchon febrifuge. But totaquina was devised as a drug suitable for distribution on a large scale. In this case it will no longer be a by-product, and its price must rise, unless the sale of quinine increases proportionately. It would be necessary to devote special plantations to its production; all the alkaloids of the bark would then be used, and the totaquina prepared would be type I. It would differ from a cinchona febrifuge produced on the same scale only by the necessary analysis, of which the cost should not be very important when spread over a large bulk of the drug. Thus, on a small scale totaquina would probably be considerably more expensive than cinchon febrifuge, while on a large scale it

the strong preparations being reserved for chronic lesions. General measures are helpful also, although it is very difficult to assess their true value. It is generally agreed that starch and fat, or the whole intake, should be restricted since the affected children often are overnourished with greasy skins. Alkaline mixtures have a clinical reputation in the treatment of seborrhoea.

Breath Odours from Alliaceous Substances: Cause and Remedy

By H. W. HAGGARD, M.D.

and

L. A. GREENBERG, Ph.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CIV, 15th June, 1935, p. 2160)

OFFENSIVE odour of the breath is often a matter of considerable importance to those afflicted, and medical advice is occasionally sought. The fact that the odour may arise from pathologic conditions in the structures of the mouth and respiratory tract is well recognized. But in many cases no definite pathologic changes are found. Moreover, the odour may not be present continuously but only during temporary periods of disturbed health or during menstruation.

It has been suggested that in such cases the substances causing the odour are of systemic origin; that the air in the lungs is tainted by aeration from the blood, or in the mouth from secretion of the substances into the saliva; or, again, that the odour arises directly from the stomach. It is more probable, however, as the evidence to be here presented also indicates, that generally the source of the odour is not systemic but local in the mouth or respiratory tract. Determination of the source is essential to any therapy.

As a phase of the problem that is directly amenable to experimental study, we have investigated the source of the odour arising after eating onion or garlic.

It is well known that there exists among different individuals wide differences in the intensity and particularly in the persistence of the odour on the breath after eating onion or garlic. Usually the breath loses its odour within a few hours, but in occasional individuals even small amounts of onion or garlic inadvertently eaten in salads, soups or sauces taint the breath for several days. Moreover, in such cases the odour often loses its typical alliaceous character after some hours have passed and, although the breath is offensive, it is difficult to identify precisely the nature of the odour. As a rule in the past little relief could be given for this condition except by disguising the odour with the use of mouth washes containing aromatic oils.

The odour from onion and garlic is due to the essential oils contained in these vegetables. That of onion is mainly allyl-propyl disulphide, $C_6H_{11}S_2$; this oil appears in garlic in small amounts, but the main constituent of the distillate from garlic is diallyl disulphide, $C_6H_{10}S_2$. In addition to these main constituents there are both lighter and heavier fractions of sulphur-bearing oils of uncertain chemical composition but all possessing disagreeable odours.

The taint on the breath after eating onion or garlic is due to the presence of these essential oils or their decomposition products in the expired air. Considerable uncertainty has existed, however, as to the manner in which the oils are discharged into the expired air. Four theories have been advanced:

1. That the oils pass into the blood stream during digestion, are then aerated from the blood in the lungs, and so pass into the expired air. For certain volatile substances such as ether, alcohol and acetone this passage from the blood to the air in the lungs is well established. This theory is the one commonly accepted also to explain the source of the odour on the breath after eating onion or garlic; occasionally it is amplified by the addition of a hypothetic secretory activity of

the respiratory mucosa by which the oil is believed to be selected from the blood and passed into the air—presumably to account for the fact that the blood, following digestion of garlic, has not been observed to smell of the oil.

2. That the essential oil appears in the saliva by secretion from the blood passing through the salivary glands.

3. That the odour passes from the stomach by way of the œsophagus (other than during eructation) and enters the breath through this channel.

4. That possibly the odour arises in part from particles of onion or garlic retained about the teeth, the tonsils and the papillæ of the tongue. Considerable attention has been given to pathologic conditions in the structure of the mouth and pharynx as sources of odour on the breath, but no one has advanced the idea that after eating onion or garlic the odour arises solely from particles retained in this locality. We, however, do advance such a theory and moreover we here substantiate it with experimental demonstration. The localization of the source of the odour to the mouth structure opens up a possibility of a remedy. No known measure could control the passage of the oils from the blood or saliva to the expired air or prevent their passage from the stomach; it is possible, however, as we shall show, to rid the mouth of the alliaceous oils.

From previous work in this laboratory with chlorine in the destruction of organic odours, attention was turned to the possibilities of this substance in the form of chloramine. After garlic had been eaten the teeth were scrubbed, the tongue brushed and the mouth rinsed with a solution made by dissolving one 4.6 grain (0.3 gm.) chloramine [Paratoluene sodium sulphon-chloramide, Chloramina, U. S. P.] tablet in each 30 c.c. of water. Particular attention was paid to the tongue, for the papillæ at the base of this structure have long come under suspicion as a source of odour from retained food particles. No odour of garlic could be detected on the breath but there remained a slight odour from the chlorine products. The question of whether the garlic odour was actually destroyed or simply masked was determined by analysis of the expired air.

Experiments were carried out first as controls to determine whether the chlorine odour liberated iodine from the pentoxide. The expired air of a subject who had not eaten garlic was first passed over the pentoxide to confirm the absence of any organic vapours. Next the teeth and tongue were washed and the mouth rinsed with the chlorine solution. The expired air was again passed over the pentoxide. No iodine was liberated; the chlorine odour did not affect the pentoxide.

In each of three experiments, 1.5 gm. of garlic was chewed and swallowed and the amount of oil in the expired air followed for one and one-half hours. During this time the oil had risen to concentrations ranging from 0.0027 to 0.0036 mg. per litre and fallen to the plateau level of from 0.0008 to 0.0011 mg. The mouth was then treated with chloramine solution as described. Repeated analyses during the next three hours showed absence of oil in the expired air. The chlorine products had deodorized the garlic particles.

Two additional experiments were carried out in which, after garlic had been eaten, the teeth and tongue were brushed and the mouth rinsed with 30 per cent solution of alcohol in water. Control experiments demonstrated that the vapours of alcohol, after the mouth had been washed with this substance, persisted in the breath for only fifteen to twenty minutes. In some proprietary mouth washes recommended for the removal of onion odour the only possible deodorant is the alcohol, which might conceivably dissolve and remove the essential oils. Our experiments show that alcohol is without effect on the garlic odour. It would appear that the only effective part played by proprietary mouth washes containing alcohol is in masking the breath by the odour of the essential oils with which they are flavoured and which are held in solution by the alcohol.

CONCLUSIONS

The odour given to the breath by onion or garlic comes from the essential oil contained in these vegetables.

The oil does not, as has been suggested, reach the breath from aeration of the blood in the lungs, from pulmonary secretion, from salivary secretion, or in air passed from the stomach. It arises solely from particles of onion or garlic retained in the stricture about the mouth.

Quantitative experiments demonstrate this fact.

The particles from which the odour arises cannot be removed completely by mechanical means; brushing the teeth and tongue and washing the mouth with soap and water fail to deodorize the breath. Similarly washing the mouth with a 30 per cent solution of alcohol is ineffective.

The breath can be immediately and completely rid of the odour by washing the teeth and tongue and rinsing the mouth with a solution of chloramine. The chlorine liberated in the mouth reacts chemically with the essential oils and deodorizes them.

It is probable that many cases of foul breath from other causes would be amenable to the same method of treatment.

Meningococcic Meningitis: A New Form of Therapy

By ARCHIBALD L. HOYNE, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CIV, 23rd March, 1935, p. 980)

SUMMARY

My experiences during the past one and one-half years seem to justify certain conclusions regarding the treatment of meningococcic meningitis. Meningococcus antitoxin has reduced by approximately 50 per cent the deaths from meningococcic meningitis at Cook County Hospital.

For many years it has been customary in the Contagious Disease Department of the Cook County Hospital to administer antimeningococcus serum intrathecally not more often than once in twenty-four hours. This plan was adhered to when meningococcus antitoxin was given. Lumbar punctures when made every twelve hours or at eight-hour intervals, as sometimes recommended, are extremely disturbing to many patients and seem to be of no added value in lowering the fatality rate.

Although cisternal punctures are much more easily performed by one with experience than lumbar punctures and are often preferred by the patient, this procedure should not be encouraged in a public hospital in which interns and residents are frequently changed. I do not believe that cisternal puncture is necessary in the treatment of meningococcic meningitis in order to secure the most efficient results. It is not essential to adopt this route for the purpose either of drainage or of administration of serum except in case of block in the spinal canal. In no instance among the entire series of 372 patients was an intraventricular puncture required.

In the brief report of a meningococcic meningitis patient treated at Cook County Hospital in 1918, the value of giving antimeningococcus serum intravenously was emphasized. Since that time it has been customary to resort to this therapy for all adult meningococcic cases admitted to my service. The value of this method is still more apparent when antitoxin instead of antimeningococcus serum is the remedy. As our experience with the antitoxin increased, larger and larger amounts of meningococcus antitoxin were given intravenously. The dose ranged from 20 cubic centimetres among the earlier cases up to 100 cubic centimetres and more during recent months. The large amounts of antitoxin intravenously explain chiefly the greater average dose of antitoxin as compared with antimeningococcus serum. On the other hand, the greater the quantity

of antitoxin given intravenously, the smaller the average amount required for intrathecal injection. The most outstanding feature of intravenous and intramuscular antitoxin treatment is the prompt response of the infection and a more than 20 per cent reduction in the period of hospitalization. In fact, it is my impression that eventually it may be regarded as entirely unnecessary to administer any serum intrathecally if sufficient antitoxin is injected intravenously. Under such circumstances lumbar puncture would be done only for the purpose of diagnosis and for drainage.

A problem is now under way to compare the efficacy of intravenous and intramuscular methods of administration supplementing intrathecal antitoxin. One young woman with a fulminating type of meningococæmia whose child died of meningococcic meningitis was treated only by large doses of antitoxin intravenously. Meningeal infection did not progress and she was discharged completely recovered on the seventh hospital day.

For the treatment of meningococcic meningitis with meningococcus antitoxin the following plan may be followed:

1. Intravenously from 60 to 100 cubic centimetres of the antitoxin is administered in from 120 to 200 cubic centimetres or more, respectively, of physiologic solution of sodium chloride or 10 per cent dextrose solution. The smaller amount may suffice for a child, the larger quantity for an adult. This form of treatment may be repeated daily if the condition of the patient seems to require it. As a rule, one large dose intravenously when therapy is started will prove sufficient by this route.

2. Intraspinaly the amount of antitoxin, undiluted, and given by the gravity method, will be governed by the volume of spinal fluid withdrawn. Usually the quantity of antitoxin administered should be less than the amount of spinal fluid released. The initial dose of antitoxin intraspinaly will usually vary from 20 to 40 cubic centimetres. Daily punctures should be made until the fluid is clear and free from organisms. At such a time the cell count of the spinal fluid will generally be less than 100.

3. Intramuscular administration of serum in an initial dose of from 30 to 60 cubic centimetres is of value, but because of the serious nature of the disease the intravenous route is to be preferred.

Reviews

THE DISEASES OF CHILDREN: A WORK FOR THE PRACTISING PHYSICIAN.—(Dr. M. Pfaundler and Dr. A. Schlossmann.) English Translation written by 61 eminent pædiatric authorities. Edited by M. G. Peterman, Sc.B., A.M., M.D. In five volumes. 1935. J. B. Lippincott Company, Philadelphia and London. Vol. I:—General Considerations, Physiology, Metabolism, Nutrition, Special Pathology. Pp. xv plus 544. Vol. II:—Pathology, Constitution, Deficiency Diseases, Diseases of Blood, Endocrine Glands, Circulatory System. Pp. x plus 512. Vol. III:—Infectious Diseases, Rheumatic Fever, Syphilis, Tuberculosis. Pp. vi plus 689. Vol. IV:—Digestive System, Respiratory System. Pp. xii plus 575. Vol. V:—Genito-Urinary System, Nervous System, Motor Apparatus. Pp. xi plus 546. Illustrated by 76 full-page plates in colour and black and white with 1,129 other illustrations in the text, of which 79 are in colour in the set of five volumes. Price, £9-9-0 per set of five volumes. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 141-12

The fourth edition of that monumental work in five volumes has been translated into English—or American—by twenty-two American collaborators and

they have added their own comments. In the preface to the English translation, it is stated, 'The development of our knowledge in the diseases of children, particularly those of infancy, has taken place largely in Germany and Austria. These countries furnished the early training of many of the pediatric leaders of the United States who, in turn, took the leadership after the world war'. Pediatric leaders in other countries will perhaps be excused if they venture to protest against this arrogant statement.

The first volume deals with the history of pediatrics, infant and child mortality, examination of the sick child, general prophylaxis, child welfare, physiology of nutrition and special pathology including diseases of the premature and weak. These points are all fully discussed and illustrated by numerous charts and diagrams. The illustrations, coloured and plain, throughout the work deserve a special word of praise; the coloured being particularly good. One reads with surprise that the active immunization of children against diphtheria is regarded as still in the experimental stage (page 116). One reads with horror on page 132, 'I remove tonsils and adenoids, when it is indicated, always without anaesthesia because it is a much greater psychic shock to the children to anaesthetise them than it is to endure the more unpleasant and painful operation'. It comes as no surprise after reading the above to find that the pre-operative use of paraldehyde per rectum finds no place in the chapter on anaesthetics. The barbarity of the operation and the neglect to mention paraldehyde are equally inexplicable in the year 1935.

The chapter on growth, structure, metabolism and nutrition of the healthy infant is very good. Vitamins in milk are dismissed in half a page and vitamine D is grudgingly admitted as such. More precise directions more clearly explained for both breast and artificial feeds would be welcomed; for instance, it is recommended that breast feeds should be discontinued for the older infant 'at an earlier period than was, . . . required a decade or two ago'.

The chapters on metabolism and nutrition of older children will be read with interest and profit. The advice about meals is excellent. More detailed culinary recipes are required; it is not clear to the English reader how vegetables are to 'be cooked in their own juice'. The pathology of the newborn is well done and beautifully illustrated. The danger of dehydration fever should be known to every doctor, nurse and parent in India. The section on icterus gravis neonatorum needs to be modernized. For the prophylaxis of gonorrhoeal blenorrhoea, 15 per cent mercurochrome is recommended!!! It is presumed that this is a misprint for 1.5 per cent. It should be corrected immediately. The chapters on diseases of premature infants is excellent; the same remarks apply to those on the physiology and pathology of puberty.

Volume II deals with the pathology of the constitution, deficiency diseases, diseases of the blood, endocrine glands and of the circulatory apparatus. The sections on developmental anomalies, obesity and emaciation, rickets, tetany and scurvy are modern and complete. We are surprised to note that the terms microcytic and macrocytic anaemias have not found their way into this work. Diseases of the endocrine glands are fully described. It is evident that the 'lower picture' referred to under figure 108, page 343, has been omitted by mistake. Too much space has been devoted to the development of the circulatory apparatus and not enough to the differentiation between functional and organic murmurs.

Volume III deals with infectious diseases. The illustrations are excellent and will be of the greatest use to students. One is surprised that there is no mention of the experiences of the active immunization of the British Army against the typhoid group of fevers and of the fact that there are two, if not three, types of paratyphoid. The therapy of dysentery in Bauer's article is lamentable; the omission of any mention of emetine for amoebic dysentery and of anti-dysenteric

serum, bacteriophage or salines for bacillary dysentery must be seen to be believed. The chapters on tetanus, encephalitis, acute anterior poliomyelitis and syphilis are excellent. Tuberculosis is well dealt with except for its prophylaxis. One reads with some astonishment on page 632 that vitamine C is especially important for resistance against infections. A brief résumé of tropical diseases helps to fill the gaps left in the treatment of dysentery but here again there is no mention of bacteriophage. The diagnosis and therapy of kala-azar is sadly out of date—even the German product, neostibosan, is not mentioned. There is nothing about atabrin for malaria nor any mention of chaulmoogra oil in the treatment of leprosy.

Volume IV is devoted to diseases of the digestive tract. The translator's note on tonsillotomy resembles our own on the same subject in our notes on Vol. I; it is—'It is considered brutal, especially in the United States, to operate without a general anaesthetic'. We ask why 'especially'? The chapter on the nutritional disturbances of infants will repay the reader. We do not understand the statement that 'The inferiority of cow's milk to breast milk cannot be attributed to the biologic nor to the chemical differences'. Under dietetics there are frequent directions '(see appendix)' but we were unable to find an appendix. The reference to the fifth type of stool—'the dark brownish, thin, liquid hunger stool' is given as Plate VI, figure 4; it should be Plate V, figure 2. Diseases of the stomach and intestines are fully described. The anaesthetic of choice for Ramstedt's operation for congenital pyloric stenosis is not ether but gas and oxygen. We do not admit that medical treatment has any place in the treatment of acute appendicitis in children. In the chapter on intestinal parasites, we were surprised to read that cimetidine is a specific against *Lamblia intestinalis*. Diseases of the respiratory organs are very well described; there are many excellent x-ray pictures of different stages of pneumonia.

Volume V deals with diseases of the genito-urinary and nervous systems. The more modern methods of biochemical investigation and the modern methods of treating various uræmic conditions are not given nor is there any mention of ketogenic diet in the treatment of pyelonephritis. The organic diseases of the nervous system are well described and the same remark applies to functional nervous diseases. The account of the neurosis of childhood is one of the best articles in the whole work.

Throughout the work, one meets with unusual expressions which presumably are American idioms, e.g., 'The diphtheria patient belongs in bed' (p. 64, Vol. III); 'She had cared for a scarlet fever patient' (p. 82, Vol. III); 'One must not, because of this, let up in the least in his attention to the temperature care' (p. 499, Vol. I). There are also a number of most unusual words, e.g., routinely, reinforced, apparatus, asphytic.

There are many excellent chapters in this work but there are others to which that description cannot apply. A great deal of it could be equally well done in a smaller space. The illustrations throughout are extremely good. The printing is very good indeed.

S. A. McS.

THE PRACTITIONERS LIBRARY OF MEDICINE AND SURGERY. Volume VII. Pediatrics. 1935. D. Appleton-Century Company Incorporated, New York and London. Pp. xxxvi plus 1211. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price (both on the cash and instalment basis), Rs. 37-8 per volume

It is not at all difficult to justify the inclusion of this volume on pediatrics in this important and valuable encyclopædia of medical practice. The whole subject of children's diseases has to be approached in quite a different way from that in which the disease of adult life and old age are considered. In the first

place environment, both ante-natal and post-natal, plays a very important part in determining the health of an infant, then diet has a far greater influence than it has on the adult, and, finally, infectious diseases assume both an actual and a relative greater importance, actual because we are more susceptible to infective agents in childhood, and relative because the child does not suffer the disabilities, mental and physical, that can be put down to the wear and tear of the human frame.

The scheme of the book is a very satisfactory one: the first chapters are on anatomy and physiology, infant hygiene, diseases and abnormalities of the newborn, the care of premature infants, and infantile nutrition. The subject of disease proper starts with 'diseases due to defective diets' and then follow a number of chapters in which the subject-matter is arranged regionally, e.g., diseases of the stomach, or according to systems, e.g., endocrine disorders. Finally, specific infections, common poisons, and helminth infestations are dealt with.

The chapters on diet struck the reviewer as being sound and useful. There was, however, here a little evidence of lack of liaison between the writers of the different sections; for example, the vitamins are discussed both in the chapter on infant food and in that on diseases due to defective diets; in the former, the pellagra-preventive vitamin is included in the B complex and there is no mention of a vitamin G, and, in the latter, vitamin G deficiency is referred to as the cause of pellagra without mention of its association with vitamin B.

Another good chapter was that on tuberculosis; this chapter has a number of excellent illustrations, mostly skiagrams. The chapter on diseases of the 'hemolytotoxic organs' (a new expression to us, but a comprehensive one) is a little disappointing. It might so well have begun with a review of the normal blood picture of infants at different ages, and then given some form of classification of blood diseases, but, with a brief apology and reference to a previous volume, the writer seemed just to drift into the subject of anemia.

The chapter on helminthic infections and their treatment is a good one, and the treatment advocated is up to date; tetrachlorethylene is given preference in the treatment of hookworm infection.

Although there are a few uneven patches, the volume has on the whole maintained a high standard. The illustrations are not numerous but are useful, and one of them has been reprinted (with acknowledgments) from the *Indian Medical Gazette*. This volume is quite up to the high standard of the earlier ones; again we remind readers that the whole series may be purchased for cash or on the deferred-payment system from Messrs. Butterworth and Company, Avenue House, Choringhee Square, Calcutta.

AN INTRODUCTION TO COMPARATIVE ZOOLOGY. A TEXTBOOK FOR MEDICAL AND SCIENCE STUDENTS.—By F. G. S. Whitefield, F.R.S., F.R.M.S., and A. H. Wood, M.A. (Cantab.). 1935. J. and A. Churchill, Limited, London. Pp. x plus 354. Illustrated. Price, 15s.

This should prove a useful book especially for students in tropical countries because many of the forms dealt with are found there. The animals chosen also make it specially useful for medical students.

The book is written by two entomologists and as a result the amount of space allotted to this branch of the subject seems somewhat out of proportion. The section on helminthology is not so good and there is an unfortunate mistake, figure 23, facing page 74, shows a scolex with hooks and is labelled *T. saginata* and when this is coupled with the statement on page 69 in the general description of cestoda that in the centre of the head '... is a rounded protuberance, the base of which is furnished with a double ring of curved and pointed chitinous hooks...' the student will be led into the error of thinking that all cestodes bear hooks on the scolex.

There are copious illustrations throughout the book and many of them are on a large scale which makes them easy to follow. This applies especially to the sections dealing with the vertebrates. There is a useful chapter on embryology in which the comparative development of all the groups is well described. This is followed by brief chapters on metabolism, heredity and evolution, the last being made clear by numerous diagrams and tables.

Finally, there is a short chapter on ecology which is of special value as it indicates clearly the importance of the study of zoology from the medical and economic points of view.

This is a book that can be recommended for use in the general scientific course preliminary to the study of medicine especially for those schools that are situated in warm countries.

P. A. M.

THE PRINCIPLES AND PRACTICE OF UROLOGY.

—By Frank Hinman, A.B., M.D. 1935. W. B. Saunders Company, Limited, London and Philadelphia. Pp. 1111 with 513 illustrations. Price, 45s.

Urology is a subject which has become so vast that it can no longer be relegated to a mere section of a textbook on general surgery. This is exemplified by Dr. Hinman's book and he states in the preface that he has written it for three reasons: firstly, because Messrs. W. B. Saunders and Company wanted a one-volume textbook on urology for medical students and general practitioners; secondly, because the writer thought he knew what was required, and, thirdly, because of a contract. The book was not to be written for specialists except to be used by them in the medical education of others.

The author has written a long and excellent book, but we consider it is much more suitable for a specialist than for medical students and general practitioners, as it contains far too much matter and is too wealthy in detail ever to be acceptable to the latter.

There are 1,111 pages of which the first 500 or so are devoted to the embryology, anatomy and physiology of the genito-urinary tract. The embryology is excellently described, and is supported by a great number of diagrams and charts, many of which are complicated in the extreme.

It is open to discussion as to whether such detailed embryology, anatomy and physiology are or are not out of place in a book of this sort. The student and the busy general practitioner want to get to the description and treatment of actual diseases as quickly as possible. It is the specialist who finds interest in examining intricate diagrams and charts such as are illustrated in this volume.

Following on these chapters, there is a very full description of the structure and function of the urinary tract, and the anomalies due to errors in its development; the genital tract is then dealt with in the same manner.

Then follows descriptions of actual diseases, each pathological condition being fully discussed, and methods of examination are given in minute detail. The chapters deserving special mention are those on the effects of urinary obstruction, prostatic enlargement, sterility, sexual neurosis, and gonorrhoea.

Dr. Hinman opens his chapter on the last-named disease with the words: 'There are many who treat gonorrhoea but few are trained to do so'. The specialist knows how true this is.

In dealing with the sterile marriage, the author states that the male partner must be cleared of blame before the female partner is examined, which is certainly correct and in conformity with modern thought. The author then describes an exhaustive examination of the male partner which is ideal, but few men would submit to it.

The book is an excellent one, and contains much detailed information on urological pathology. It is written in an easy style and printed on good paper.

The illustrations must be accorded special mention. They are very good indeed, and the charts and diagrams have been most carefully drawn with scrupulous attention to detail.

H. E. M.

A MANUAL OF ORGANIC CHEMISTRY: FOR MEDICAL STUDENTS.—By S. Ghosh, M.Sc., D.Sc., F.R.S.E., and T. C. Boyd, M.R.C.P.I., F.R.C.S.I., D.P.H., F.I.C., Lieutenant-Colonel, I.M.S. Second Edition. 1935. Scientific Publishing Company, Calcutta. Pp. x plus 257. Illustrated. Price, Rs. 4-12

THE second and revised edition of this little book has now made its appearance. It is as the authors state intended for medical students, a class difficult to cater for as regards chemistry. At the present date the medical curriculum is as much as the student can assimilate and the demand on the specialist teacher to present his subject in a short and concise way is not easy. This book designed for Indian students, especially those of Calcutta and Patna, meets this need in large degree. The extensive use of graphical formulae is a great asset. It not only aids the memory but also brings before the eye the chemical relationships of the different substances met with in the living organism. The authors have picked out here and there substances of medical interest with a short note on their significance which should help to interest the student and above all make him realize the significance of chemistry in medicine. It should never be forgotten that the average medical student regards his pre-clinical studies as so much ground to be got over.

The interested student with a knowledge of inorganic chemistry should be able to obtain the essentials with comparative ease from this book, which is well got up and can be confidently recommended.

H. E. C. W.

DIABETES MELLITUS—A CLINICAL STUDY.—By T. A. Oliver, M.A., M.D., F.R.C.P. 1935. John Bale Sons and Danielsson, Limited, London. Pp. 120. Price, 3s. 6d.

THIS is a well-written and compact little volume dealing with the practical aspects of diabetes mellitus.

The author, who has fifteen years of clinical experience behind him, very rightly lays stress on the variations in the different clinical types of the disease that are met with. In view of the fact that the responses to treatment in these different types are different, an early recognition of the particular type of diabetes one is dealing with is essential for the successful management of the case. Chapters III and IV, more particularly the former, which deals with this subject in a clear and explicit style will amply repay perusal.

We consider it to be a very useful book for students and practitioners.

J. P. B.

BENIGN, ENCAPSULATED TUMOURS IN THE LATERAL VENTRICLES OF THE BRAIN.—By Walter E. Dandy, M.D. 1934. Baillière, Tindall and Cox, London. Pp. viii plus 189, with 83 figures. Price, 20s.

THE tumours in the lateral ventricles causing signs and symptoms the author divides into (1) those that are benign and encapsulated, and (2) those that are invasive or otherwise malignant. The selection of the benign tumours in the lateral ventricles for the basis of a thesis is due to the fact that they alone offer a permanent cure by extirpation. A series of fifteen cases of primary benign encapsulated tumours in the lateral ventricle is reported. All but one were totally removed at operation, with three deaths. Twenty-five additional cases have been collected from the literature and are fully reviewed. The clinical signs and symptoms have been analysed in all cases and the methods of diagnosis and operative removal fully discussed. The other types of tumours are also mentioned and treated from their importance in differential diagnosis. The text is profusely illustrated with photographs of cases, tumours, photomicrographs of sections of the tumours, drawings and some excellent ventriculograms and the whole makes very interesting reading. Both the author and publishers must be congratulated on the production of a useful little book which should arouse interest in the surgical and diagnostic story of a group of tumours occupying the lateral ventricles of the brain.

Abstracts from Reports

RESOLUTION REVIEWING THE REPORTS ON THE WORKING OF MUNICIPALITIES IN BENGAL DURING THE YEAR 1932-1933. (GOVERNMENT OF BENGAL, LOCAL SELF-GOVERNMENT DEPARTMENT)

Public health.—Municipal authorities generally showed energy in taking measures for the prevention and control of epidemic diseases. Inoculation against cholera and vaccination for smallpox were extensively resorted to, and antimalarial measures were widely adopted in co-operation with *Pallimangal Samitis* and other local associations. A smallpox epidemic at Burdwan caused a considerable number of deaths, but the municipality took effective measures in conjunction with the district board, and by resorting to house-to-house vaccinations and chlorination of filtered water, brought the epidemic under control. More prompt action on the part of the municipality immediately after the outbreak of the epidemic might have prevented much loss of life. The Bogra municipality experienced considerable difficulty in dealing with a smallpox epidemic, which was said to have originated in Calcutta, and they had to take substantial help from the district board. An antimalarial scheme was started at Raniganj with the assistance of the public health department and with the help of a Government grant. The Narayanganj municipality took effective steps to remove water-hyacinth from tanks and ditches,

and, by resorting to vaccination on a large scale, was able to reduce the number of deaths from smallpox during the year to four. At Dacca there was a very satisfactory increase in the number of revaccinations from 7,719 to 21,620, while primary vaccinations rose from 4,905 to 6,305. Birnagar worked on scientific lines in fighting malaria, although progress was hampered by lack of funds. Berhampore opened one leprosy and two kala-azar centres, and treated a large number of patients free of charge. It also conducted health examination of the children in its free primary schools, and reported the results to parents and guardians with advice to seek medical help where necessary. Anti-kala-azar and antimalaria centres were opened at Chandrakona and antimalaria societies were formed at Chandrakona and Khirpai. With a view to safeguarding the inhabitants of Chittagong against rabies, the municipality destroyed 353 suspected and ownerless dogs by the administration of poison.

As in the previous year most of the municipalities took steps to improve sanitation by filling up, clearing or disinfecting insanitary tanks, ditches and *dobas* and by removing undergrowth and obnoxious vegetation. Seventeen municipalities in the Presidency Division utilized street refuse, road sweepings and rubbish, with very satisfactory results, in filling up ditches and other insanitary excavations, and notices were freely issued on owners to clear jungles and reclaim tanks. The

Food Adulteration Act appears to have been very unevenly administered. In the Burdwan Division it is reported to have become more or less a dead letter in most municipalities. The Commissioner of the Presidency Division remarks that only 60 prosecutions had been reported, and that the laboratory at Khulna was not being made use of by the neighbouring municipalities. In the Darjeeling district, in which 50 prosecutions took place during the year, the Act appears to have been vigorously administered, but the number of prosecutions in the remaining districts of the division was only 38, the number being nil in the municipalities of Jalpaiguri and English Bazar (Mald). In Dacca 85 persons were prosecuted and 297 mounds of adulterated foodstuffs were destroyed, while the Chittagong and the Faridpur municipalities prosecuted 81 and 71 persons, respectively. On the other hand, Mymensingh prosecuted only 23 persons, and only 4 sellers of adulterated foodstuffs were prosecuted by the Barisal municipality. Generally speaking, district boards displayed much more zeal than municipalities in this respect and several district boards complained of the failure of urban authorities to co-operate in the prevention of adulteration. In towns, where retail trade is extensive, municipal executives are often reluctant to antagonize influential tradesmen by insisting on a high standard of purity in foodstuffs. It is to be hoped that all municipalities will, in future, in the interest of the health of the community, make adequate use of their powers of prosecution under the Food Adulteration Act.

ADMINISTRATION REPORT OF THE PUBLIC HEALTH DEPARTMENT FOR THE YEAR 1931. GOVERNMENT OF TRAVANCORE

It was during the year under review that the public health department was brought into being with its present constitution. Till 5th September, 1933, two separate agencies were functioning, *viz.* the sanitary department and the public health organization. The former dealt only with three phases of public health work—vaccination, rural sanitation and registration of vital statistics. Under the guidance of Dr. W. P. Jacobs, Honorary Adviser, Public Health, the latter organization was working a programme of activities comprising a hookworm treatment campaign, public health education, epidemiological and vital statistical investigations, health unit work, medical entomology and plague control measures. It was considered necessary by Government, in the interest of an efficient public health administration of the State, to effect an amalgamation of the sanitary department with the public health organization so that all the activities might be co-ordinated under a single director. Such a combination was also facilitated by the fact that the services of four medical officers of health with special foreign training in public health work were available. Government accordingly sanctioned the amalgamation of the sanitary department and the temporary public health organization into a new 'Public Health Department' placed on a permanent footing with effect from 6th September, 1933, its immediate control being vested in a Deputy Director of Public Health. The bacteriological laboratory under the medical department was re-constituted as the public health laboratory, embracing the sections of the government bacteriologist, the chemical examiner to government, the public analyst under the food adulteration regulations, the hookworm laboratory and the vaccine depot. The public health laboratory thus newly formed also became a part of the public health department. The year under review is therefore the first year of public health activities undertaken by a co-ordinated and unified organization.

The programme of work included the following:—

- (1) Registration of vital statistics.
- (2) Control of communicable diseases.
- (3) Vaccination.

- (4) Plague control measures.
- (5) Malaria and filariasis surveys and investigations including mosquito and filariasis control.
- (6) Hookworm treatment campaign.
- (7) Public health laboratory.
- (8) Health unit, Neyyattinkara.
- (9) Rural sanitation.
- (10) Public health education.

KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND: FOURTH ANNUAL REPORT, 1934

This fund is the nucleus of anti-tuberculosis activities in India and represents the national effort to fight tuberculosis. The fund would enlarge its scope of work if money were available, but with its limited resources its activities have to be restricted. At present they direct their energies to bringing home to the public the necessity and urgency of the problem. They have set themselves to organize a propaganda and educative campaign in the Provinces of British India as well as in the Indian States with a view to educating the people about the causes and preventive measures against tuberculosis, and to creating a public conscience so that efforts may be made in all directions to fight the disease.

During the year under review the educative and propaganda campaign was carried out through 16 Provincial and State Anti-Tuberculosis Committees, Medical, Public Health and Education Departments, Sanatoria, Medical Colleges and Schools throughout India.

The outstanding event of the year was the bringing together of tuberculosis workers from all over India to afford them an opportunity of meeting and exchanging views. At this conference various papers were read and stimulating discussions took place. A report of the transactions is in press and will soon be available.

The chief aim of the fund is to organize a propaganda campaign against tuberculosis and to publish suitable material for distribution and utilization by various agencies and departments engaged in the prevention and control of tuberculosis. We have now a large amount of propaganda material in the shape of charts, picture posters, pamphlets, leaflets, films and slides, etc.

The attractive and multi-coloured picture posters on causes and prevention of tuberculosis, which were published last year for the first time, have proved very popular and another 5,000 copies of each had to be re-printed, while the colours have been improved. These have been widely distributed by the Provincial Anti-Tuberculosis Sub-Committees, Surgeons-General and Inspectors-General of Civil Hospitals, Directors of Public Health, Directors of Public Instruction and Chief Medical Officers of Railways, etc. These have been in such great demand that another 5,000 copies of each of these picture posters have had to be printed.

The printing of a set of six pictorial charts on signs and symptoms of tuberculosis has also been sanctioned and is under preparation.

The following two new films on tuberculosis were purchased during the year:—

1. *Posture* (two reels) with titles in English.
 2. *Consequences* (one reel) with titles in English.
- Standard size.

The first film, *Posture*, presents new material on and its relation to physical fitness. The first reel is a more or less general showing, through the medium of the bony framework of the body, the effect of posture on the body. The second reel is devoted to showing important posture exercises. The other film on *Consequences* is based upon the slogan 'Early Discovery—Early Recovery', showing in vivid manner the cause, diagnosis and cure of tuberculosis.

The films on tuberculosis have been in great demand and exhibited at a large number of places in various Provinces and States. The film on *Causation and*

Prevention of Tuberculosis, prepared locally by us, has proved popular and two copies of it were sold during the year.

Propaganda cinema lorry.—A cinema lorry has been fitted up at headquarters; this will tour in the Provinces with a view to carrying out an intensive propaganda campaign against tuberculosis by means of cinema films. There will be a qualified medical man in charge of the lorry who will give lectures and show films to the audiences in the districts and villages.

The fund aims at improving the training of medical students and medical practitioners, so as to equip them to give the unfortunate victims the benefit of up-to-date methods of diagnosis and treatment.

Treating the disease early and properly is rewarded by arrest and cure. With this end in view, grants are made to several medical schools from time to time and a special training course in tuberculosis has been arranged at Calcutta with the co-operation of Lieutenant-Colonel A. D. Stewart, Director of the All-India Institute of Hygiene and Public Health, Dr. A. C. Ukil, Lieutenant-Colonel Boyd, the Principal of the Medical College, Calcutta, Dr. K. S. Ray, the Superintendent of the Jadabpur Sanatorium, Dr. Galstaun, the Radiologist of the Medical College and Dr. Remfry, Honorary Secretary of the Bengal Tuberculosis Association, to whom our thanks are due. The class will consist of 25 medical practitioners from all parts of India who have been selected from over 100 applicants, and will be held from the 4th to 23rd February, 1935. The demand has been so keen that another course is contemplated.

The fund aims at arousing public opinion and enthusiasm to fight tuberculosis. There are some hopeful and encouraging signs. We find that all over India, especially in big cities and towns where the problem is acute, people are talking about the tuberculosis problem, the press is writing about it and cities are waking up. To name a few, Agra, Ajmer, Allahabad, Cawnpore, Delhi, Jullundur, Multan, Ranchi, Shillong, and many others scattered far and wide are setting up tuberculosis dispensaries, clinics or hospitals and are raising funds running into thousands of rupees. We find that the railway authorities in India are also contemplating schemes of prevention and treatment and we dare to say the day is not far distant when Central and Provincial Governments will contemplate how best to protect their employees and their families from falling victims to this disease. Such an awakening cannot but be a source of satisfaction to all who have the welfare of India at heart.

QUARTERLY REPORT OF THE MYSORE STATE DEPARTMENT OF HEALTH, 1ST JANUARY TO 31ST MARCH, 1935

Stations for the study of malaria

A new research station financed by the Rockefeller Foundation was opened from 1st January, 1935, at Gargeswari, T.-Narsipur Taluk, 15 miles from Mysore, to study the causes for the low incidence of malaria in this area which is similar to the Nagenahalli area in all respects. Five villages all within a distance of a mile of each other situated on the banks of the two rivers Cauveri and Kapini are under study. The spleen rates in these five villages vary from about sixty-five per cent to two per cent. The anophelines of the carrier species will be investigated with respect to the possible existence of races with different feeding habits to account for this vast variation in the incidence of malaria within such narrow limits.

The scheme for the experimental control of malaria in 10 of the heavily malaria-affected villages round about Mandya town was sanctioned by Government under joint agreement with the Rockefeller Foundation. The work of this special unit was started during the quarter and the 10 villages have been selected for malaria control by anti-larval measures with Paris green. It is proposed to control anopheline breeding

within a quarter of a mile round each village. This area is divided into six sections and each section is Paris-greened once a week by one man working morning and afternoon for six days in the week. The work of the field man is checked by one assistant sanitary inspector and the officer in charge.

Four adult catching stations have been selected for each village where anopheline mosquitoes will be caught once a week, as usual. Spleen and blood examinations have been made at the start and it is proposed to repeat these half-yearly. Spleen examinations in a few selected villages in the same area are also made to serve as controls.

A one per cent Paris green mixture with ash and road dust as diluent is used. The mixing is all done at the central office at Mandya and the prepared mixture, enough for a week, is stocked in each village. It is estimated that the cost of malaria control for these 10 villages will be about Rs. 800 per village per year.

The control work in the three study stations is being continued, as usual. The work of all these stations was inspected by the Superintendent, Dr. Paul F. Russell of the Rockefeller Foundation visited the malaria stations with the Consultant in Health during the quarter.

The possibility of using the powdered root bark of one of the indigenous plants *Mundulea suberosa* growing wild in all parts of the State was investigated during the quarter. The first laboratory trials were done by the late Dr. Kunhi Kannan who discovered this during his field studies as a commonly used fish poison.

During the present investigation different samples of the powder supplied by the entomologist of the Agricultural Department were tried in the laboratory and the sample from Banavar was found to be most toxic being lethal to both the culex and anopheline larvæ in 24 to 48 hours. But the powder was practically ineffective against these larvæ under field conditions. But small fish, tadpoles, and frogs were effectively destroyed in the areas sprayed with this powder.

The mosquito control work in the mining area of the Kolar Gold Field was inspected on the request of the chief medical officer of the mines. The method adopted for mosquito control in the area is (1) permanent minor engineering works wherever possible, (2) anti-larval measures by spraying pesterine, and (3) house inspections for possible culex breeding places.

ANNUAL REPORT OF THE CHEMICAL EXAM- INER TO THE GOVERNMENT OF MADRAS FOR THE YEAR 1934

HUMAN POISONING CASES

OLEANDER heads the list with 41 cases, opium or its alkaloids come next with 24 cases, closely followed by datura or mydriatic alkaloid with 23 cases. There has been a surprisingly large increase in the datura cases.

The following cases are selected as of interest:—

Mercury.—(1) A man was suspicious of his wife's conduct and there had been frequent quarrels between them. One evening on returning from work he found his wife absent from home. He went in search of her, found her and asked her to return home to serve him food but she refused. He went home and began to eat the food that had been prepared by his wife early in the evening. It had a queer taste and suspecting that his wife might have poisoned it, he reported the matter to the village magistrate. It was forwarded to us and we found in it about 17½ grains of corrosive sublimate.

(2) A man was given poisoned milk and he died four days later. In the viscera only very minute quantities of mercury were found whereas in the vomit that had been collected there was 25 grains of corrosive sublimate.

(3) A man, aged 40 years, was arrested and escorted by the police from Palni to Melur. On the way his escort allowed him to drink coffee at a hotel after which he had severe abdominal cramps and vomiting.

He was admitted in hospital where he died about a fortnight later. Before his death he confessed to having swallowed perchloride of mercury in the coffee. In this case we found extremely minute quantities of mercury in the viscera but one of the vomits sent to us showed about 1-1/6th grains of corrosive sublimate.

(4) In two cases in each of which death was very rapid we found large quantities of corrosive sublimate in the viscera—30 grains in one case and 50 grains in the other.

It is interesting that in fatal cases of mercuric chloride poisoning, if the victim lives for some time after taking the poison, only very small amounts are still to be found in the viscera.

Copper.—There were four cases of poisoning by copper sulphate all suicidal, two of which proved fatal:—

(1) A man attempted to commit suicide by swallowing copper sulphate. He was removed to hospital. In his stomach contents we detected copper equivalent to about a quarter grain of crystalline copper sulphate. The man recovered.

(2) A woman who, as a remedy for abdominal pains, took some blue stone in butter-milk was removed to the hospital in a collapsed condition. From one of the vomits preserved we obtained copper equivalent to about two grains of crystalline copper sulphate. She recovered.

(3) A man, aged 25, unable to bear pain in the abdomen swallowed copper sulphate to put an end to him-self. He was removed to hospital at 7 p.m. and died at 4 a.m. the next morning. We found in his viscera copper equivalent to about 25 grains of crystalline copper sulphate.

(4) A young man, aged 19, a student, swallowed some copper sulphate from the laboratory. He died the same day. We found in his viscera copper equivalent to about 25 grains of crystalline copper sulphate.

The post-mortem appearances of poisoning by copper sulphate are worthy of note. In each of the above two fatal cases rigor mortis was present at the post-mortem examination. The features were pinched and the pupils were semi-dilated. The pericardium contained some serous fluid. The right side of the heart was full and the left side was empty. The pulmonary vessels were engorged and both lungs showed intense congestion. There was also congestion of the liver, the gallbladder being half full. There was also intense inflammation of the stomach, the mucous membrane being corroded in places with patches of hæmorrhage and necrosis. The intestines were intensely inflamed. The gastro-intestinal tract was stained blue in numerous places. The brain and the dura were also congested.

Powdered glass.—A servant, at the instigation of some persons who wanted to kill the inmates of the house where he was serving, while the milk was boiling put powdered glass into it. A little later, a portion of the milk was used to feed the baby and while the rest of the milk was being poured into another vessel particles of glass were found at the bottom. The child did not suffer from any symptoms probably because the glass powder had settled at the bottom of the milk. The stone used for powdering the glass, a coconut shell in which the powder was conveyed to the house, the vessel with the milk and some powder collected from the place where it had been originally pounded, were sent to us and we found powdered glass in each of the items.

Barbituric acid.—A woman, aged 30, was brought to the hospital with a history that she had swallowed some seven or eight tablets of some-yl. She was drowsy, not answering questions; her pupils were slightly contracted, equal and reacted to light. The conjunctival reflex was present. The pulse rate was 115 per minute, regular and of fair volume and tension. The respirations were 23 per minute and regular. In the stomach wash sent to us we detected a derivative of barbituric acid. The woman recovered.

Aconitine.—(1) Three children were given a decoction of some root with castor oil. They became restless and developed tingling of lips and tongue, burning sensation in the stomach with numbness in the body and inability to walk. Two of them died. From the stomach of one of the victims we obtained aconitine but could not find any in the stomach of the other. There is little doubt that both died of aconite poisoning. Our inability to find it is noteworthy as showing how difficult it may be to find it in the stomach even when the patient has been poisoned by it.

(2) There was a case of ordeal by poison. A gold necklace was lost in a house. A man who was said to be an adept in the occult arts was brought by the owner to trace out the culprit. Ten possible suspects were assembled and each of them was given something to chew in betel leaves. One of them had vomiting and purging but recovered in hospital. Some pieces of root were sent to us in connection with this case and we identified the root to be aconite.

Strychnine.—A man died suddenly with 'epileptic fits' and it was only because the inmates of the house were his enemies that the viscera were forwarded to us. We detected strychnine in the viscera.

Picrotoxin.—A woman was found at bedtime to be suffering from pain in the stomach with vomiting and convulsions. She died at about 4 a.m. the next morning. The viscera were sent to us but we had no information as to the nature of the poison swallowed. We obtained from the viscera an acid ether extract which (1) was crystalline, (2) reduced Fehling's solution, (3) killed a frog with convulsions, (4) gave a brick-red colour on treatment with potassium nitrate and concentrated sulphuric acid followed by addition of solid potassium hydroxide, and (5) gave a bright red colour on treatment with a solution of benzaldehyde in absolute alcohol followed by the addition of concentrated sulphuric acid. We did not obtain any alkaloid from the viscera. We therefore concluded that the acid ether extract we had obtained was picrotoxin, the active principle of *Cocculus indicus*.

Eucalyptus oil.—(1) A man fell accidentally and feeling giddy as a result of the fall is stated to have taken as a remedy about one ounce of eucalyptus oil. About an hour later he was taken to hospital with severe pain in the stomach and nausea. His pulse rate was 116 and respirations 28 per minute. The stomach wash sent to us showed the presence of eucalyptus oil. The man recovered.

(2) In another case death was attributed to swallowing a few drops of eucalyptus oil on sugar. The post-mortem report stated that death was due to acute influenzal pneumonia. We did not detect eucalyptus oil or other poison in the viscera.

Eucalyptus oil in this country does not seem to be such a poisonous substance as in England; this is possibly due to adulteration.

Madar juice.—There were two cases of death from drinking madar juice. From the viscera of each of the two cases we obtained the reactions of madar juice as described in the annual report for 1933.

As the post-mortem appearances with this poison have been but little described we give them in detail.

(1) In the first case (a woman aged 25), the post-mortem signs were as follows:—The eyes were closed. There was discharge of blood from the nostrils. The left side of the heart was empty and the right side contained a small quantity of blood. Both the lungs were congested, red in colour and of soft consistency. The liver was normal with the gallbladder empty. The spleen and the kidneys did not show any marked signs. The stomach was distended, the lesser curvature being congested, and containing four ounces of a brown liquid. There were no appreciable signs in the intestines. The uterus was normal and the bladder empty. The brain substance was softened due to decomposition.

(2) In the second case (a man, aged 65) the body was decomposed but the following signs were present:—There was no discharge from the nostrils or mouth.

The pleura was adherent on the left side and also at the base of the right lung. This is presumably an old scar. The pericardial cavity contained 2½ ounces of red fluid. There was clotted blood in the right side of the heart and the left side was empty. The heart was dilated. The lungs were grey and friable. The liver, spleen and kidneys were normal. The outer surface of the stomach was congested. The intestines were decomposed. The membranes of the brain were vascular and the surface of the brain was reddish in colour.

Gloriosa superba.—A man, aged 45, was found with violent gastro-intestinal symptoms in the morning and, when questioned by his neighbours, stated that he had eaten the root of *Gloriosa superba* in order to commit suicide. He died between 4 p.m. and 6 p.m. the same day. At the post-mortem examination the body was somewhat decomposed. The eyes were half open and there was frothy blood-stained fluid from mouth and nose. The features were relaxed. The heart was dark red, the right side of the heart containing dark fluid blood mixed with clots and the left side only a few clots. The lungs were soft, dark blue and congested. The pleurae were also congested. The peritoneum was injected. The liver was dark red and congested and the gallbladder contained about a quarter ounce of thick bile. The spleen was dark blue and soft. The kidney was dark red and congested. The mucous membrane of the stomach was slightly injected and there were about two ounces of thick greyish-white liquid mixed with small bits of some white vegetable inside the stomach. The intestines were slightly injected. The bladder contained half an ounce of reddish urine. The membranes of the brain were congested and the brain substance was soft and congested. The viscera were sent to us. We obtained from them a poisonous extract similar to that from *Gloriosa superba*.

'Karu Veeerathalai' leaves (Elæodendron glaucum, Pers.).—We received last year a case of poisoning by drinking a decoction of the leaves of the plant. The symptoms were not stated. At the post-mortem examination the heart cavities were found to be empty. The lungs were soft and slate-coloured; the stomach and intestines were congested with a thick yellow liquid in the latter, and the membranes of the brain were vascular. We obtained from the stomach a poisonous resin similar to the poisonous extract obtained from the leaves and bark of *Elæodendron glaucum*. This plant is a shrub occurring in the hotter parts of India. In Watt's *Dictionary of the Economic Products of India* it is stated that the root is a 'specific' against snake bite (whether internally or externally it is not stated). The bark is stated to be used in native medicine and to be a virulent poison. The leaves are said to be used as a fumigant to rouse women from hysterical fits. The leaves and bark were examined in this laboratory and both yielded a poisonous resin which gave in chloroformic solution with acetic anhydride and sulphuric acid a green colour (Lieberman reaction). The resin was found to be freely soluble in chloroform and sparingly soluble in ether and in petroleum spirit.

'Jammi leaves' (Prosopis spicigera L.).—Some leaves were received said to have been used in a suspected poisoning case but we did not however detect poison in the viscera. The leaves examined here gave a poisonous acid ether extract which did not give the Lieberman reaction for resin. It gave a brown colour when dissolved in acetic acid containing ferric sulphate and floated on sulphuric acid containing a trace of iron (Keller's reaction). The extract did not reduce Fehling's solution. The leaves were identified by the agricultural botanist, Coimbatore, to be those of *Prosopis spicigera* L.

Oleander.—Thirty-six of the forty-one cases in which oleander was detected were fatal. The symptoms of oleander poisoning, so far as can be gathered from the histories furnished, appear to be tingling of tongue, shivering of hands and feet and later of the whole body, epigastric pain, vomiting, in a few cases purging, rapidity and failure of pulse, and asphyxial symptoms.

In some cases convulsions also occurred. Unconsciousness set in only towards the end.

The post-mortem notes revealed that in about half of the fatal cases the heart was contracted and all its chambers were empty. In about a third of the cases the right side of the heart was filled with dark blood and the left side of the heart was empty. In practically all the cases the lungs were congested. There was also congestion of liver, spleen, kidneys and brain in most of the cases and the stomach and intestines showed patches of congestion.

The cases we received were mostly suicidal and it seems as if oleander is taking the place of opium as the poison of choice for suicide.

Scorpion sting.—Cases of death from scorpion sting are very rare. What would appear to be a genuine case occurred in a man aged about 38 years who was stated to be apparently in good health. He was stung by a scorpion at about 3-30 p.m. and died in 10 minutes. The post-mortem examination revealed not only evidences of heart failure but also the presence of caseating tubercles at the apex of the right lung. The scorpion that stung him was enclosed in a match box and forwarded to us along with the viscera. As we were not told in the letter of advice whether the scorpion sent to us was a live one or a dead one, we opened the match box with due precautions only to find a dead scorpion. It was of ordinary size about two inches in length from the head to the tip of the tail—not a specimen the sting of which could have been expected to prove fatal to a normal adult. We did not find any poison in the viscera.

ANNUAL REPORT OF THE DIRECTOR, LEAGUE OF NATIONS, HEALTH ORGANIZATION, EASTERN BUREAU, SINGAPORE, FOR THE YEAR 1934

We have received the annual report of the director of the League of Nations, Health Organization, Eastern Bureau, Singapore, for the year 1934.

This report does not lend itself to abstraction but it is an extremely valuable production and all health authorities in Eastern countries should be in possession of it as it gives a very useful summary of the prevalence of important epidemic diseases throughout the entire Eastern area which includes all countries from the East African coast to Japan and Australia.

REPORT OF THE COMMISSIONER OF PUBLIC HEALTH, SHANGHAI MUNICIPAL COUNCIL, PUBLIC HEALTH DEPARTMENT, FOR THE YEAR 1934

Despite an abnormally hot summer with a rainfall approximately eleven inches below the average the year has, on the whole, been comparatively free from any major communicable or other diseases. The foreign mortality rate, namely, 11.34 per mille, which includes all Eastern races other than Chinese, compares favourably with that of the principal cities throughout the world, though it is only fair to point out that, to some extent, the Settlement is in a favourable position inasmuch as many of the older inhabitants retire and also some of the more youthful return to their homes, with the result that a proportion of its mortality (which would otherwise increase the death rate) occurs elsewhere.

The Chinese death rate of 14.25 per mille would also be described as a very favourable figure were it not for the fact that faulty registration and other factors, over which the department has no control, cause this figure to be of no real value in judging the general health of the population.

In regard to communicable diseases, during the early part of the year smallpox was prevalent, reaching what is usually described here as the epidemic state of 21 new cases per week during the months of January and March. However, considering the population factor

the epidemic was a very minor one and of short duration.

The practical absence of cholera for the second year in succession was a notable fact. Possibly, since the regular cycle has been broken, we may hope that next year, which if the cycle followed its normal course would be one of severe incidence, may also be one of comparative freedom.

It is to be noted as a matter of interest that such periods of interruption in the cycle are to be found during the years 1896 to 1902 and 1907 to 1912, and that the only cyclical phenomenon observed in Shanghai during the last few years is that years of epidemicity not infrequently follow on two years of increasing incidence, and not so far as can be seen on years of slight incidence. However, it is impossible to predict on a matter of this importance without further data than are available at the present time.

In spite of the absence of cholera as chronicled above, the incidence of diseases of the enteric group, such as typhoid and the dysenteries, remains too prevalent. Typhoid shows a steady incidence which does not seem to have been materially affected during the last few years by the various prophylactic measures taken, and while the increase is due in part to improved notification it would seem that some further steps are necessary for its prevention. One important step may be represented by the measures proposed for the general pasteurization of milk.

ANNUAL REPORT OF THE HEALTH DEPARTMENT, MUNICIPALITY OF SINGAPORE, FOR THE YEAR 1934

Cholera, plague and smallpox

ONCE again a year practically free of cholera, plague and smallpox has occurred.

There has been no case of cholera for six years, and, with the exception of a single isolated case in 1933, no plague for five years.

There was one case of smallpox. It was of the hemorrhagic variety and the patient, an elderly Chinese woman, died a few days after admission to hospital. Though exhaustive enquiries were made, the source of origin could not be traced and no connection with any previous case could be established. The patient's home was an insanitary plank-and-attap hut in Serangoon Road. It was impossible to disinfect it properly so that it was deemed safest to demolish and burn it. Contacts from it and neighbouring huts, to the number of 27, were sent to St. John's Island to undergo the usual quarantine period.

With regard to plague prevention generally, the usual modified rat trapping was carried on throughout the year—both in the Port and the town proper. Three thousand seven hundred and thirty-six rats so trapped were dissected, but none were found infected.

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1933. BY DR. R. B. KHAMBATA, D.P.H., DIRECTOR OF PUBLIC HEALTH, BENGAL

Cholera

CHOLERA claimed 29,242 deaths in 1933 giving a death rate of 0.6 per mille against 33,910 deaths and a rate of 0.7 per mille in 1932, thus showing a decrease of 14.3 per cent.

It was 60.0 per cent less than the average of the previous quinquennium (1.5). 2.4 per cent of the total deaths in the province in 1933 was due to cholera. Reports of cholera deaths were received from 527 out of 672 circles of registration and from 7,897 out of 86,360 villages in the province against 587 out of 672 circles and 10,087 out of 86,360 villages, respectively, in the previous year.

In January 1933, 2,421 deaths from cholera were reported. The mortality steadily rose up to 8,287 in April. It slowed down to 306 in September. From

December it again began to rise. Compared with the previous decennium, the death rate was lower in all the months.

Preventive measures

Inoculation.—1,232,530 cubic centimetres of anti-cholera vaccine was issued in 1933 against 1,001,690 cubic centimetres in the previous year. The total number of inoculations performed was 1,306,643 against 952,105 in 1932.

Disinfection.—146,910 wells and 30,207 tanks were disinfected against cholera in 1933 in addition to 3,242 river ghats, 466 houses and one *jhil*.

Inoculation of pilgrims to the Puri Rathajatra, Ganga Sagar mela and the Haj.

Assistance was given to various local bodies in anti-cholera work.

Magic lantern and bio-scopic film demonstrations together with the distribution of leaflets and posters on cholera were also carried out.

Smallpox

Smallpox claimed 15,426 victims in the province in 1933 against 7,910 in 1932. The death rate was 0.3 per mille in 1933 against 0.2 in 1932, and 0.4 the mean of the previous five years, showing a reduction of 25.0 per cent against the latter and an increase of 50.0 per cent in the former. Smallpox was responsible for 1.3 per cent of the total provincial mortality against 0.77 in 1932. Five hundred and two registration circles and 4,359 villages were affected with smallpox in 1933 compared with 366 circles and 1,995 villages.

From December 1932 smallpox was on the increase, reached its height in April 1933 and declined steadily from May, the mortality came to its lowest in November. In December 1933 it again began to rise. As compared with the previous decade, the death rate in 1933 was lower in every month except in February.

During the year there has been a decrease in the number of vaccinations by 45,889 persons. There was a slight increase in the number of primary vaccinations and of children successfully vaccinated under one year and one year and under six years. Owing to outbreaks of smallpox in several districts during the year, the total number of vaccinations during the recess season has increased by 185,975 operations over that of the previous year.

Plague

In Bengal only one death from plague occurred, *i.e.*, in Calcutta in December 1933.

Fevers

Deaths from fever numbered 812,393 in 1933 against 691,513 in 1932. The death rates from fever were 16.3 per mille in 1933, 13.8 in 1932 and 14.4 during the last quinquennium. The fever death rate in this year thus increased by 18.1 per cent compared with the previous year and by 13.2 per cent with the last quinquennium. There was a general increase of death rates from all kinds of fever in 1933. Fevers accounted for 67.8 per cent of the total provincial mortality against 67.6 per cent in the previous year.

Malaria

Malaria was responsible for 413,922 deaths with a death rate of 8.3 per mille in 1933 against 327,386 deaths with 6.6 death rate per mille in 1932. The number of deaths thus increased by 86,536 showing a rise of 25.7 per cent in the death rate. Malaria accounted for 50.9 per cent of total fever mortality and 34.5 per cent of the total provincial mortality in 1933 against 47.3 and 32.0 per cent, respectively, in 1932.

13,329.4 pounds of quinine was consumed in 1933 against 9,031.3 in 1932. Except Burdwan, Hooghly and 24-Parganas, all other districts in Bengal showed increased quinine consumption. The fever indices fell, however, only in the districts of Calcutta and 24-Parganas in the year under report. The average quinine consumption per head of population was highest in Chittagong as in the previous year.

Kala-azar

Thirteen thousand four hundred and forty-seven deaths from kala-azar were registered in 1933 with a death rate of 0.27 per mille. Six hundred and eighty-nine deaths were returned from towns, of which 223 occurred in Calcutta and 12,758 in the rural areas. Compared with 1932, the death rate in all Bengal towns increased by 11.1 per cent but in Calcutta it decreased by 5 per cent. In rural areas, the number of deaths increased by 2,684, the death rate having increased by 28.5. Twenty-nine towns returned rates above the provincial urban average (0.2), the highest mortality from kala-azar (2.1 per mille) having been registered in Kalna. Out of 118 towns, 45 did not record any death from kala-azar. Kala-azar accounted for 1.6 per cent of fever deaths and 1.1 per cent of the total provincial mortality against 1.5 and 1.04 per cent, respectively, in 1932.

Dysentery and diarrhoea

The total number of deaths reported from dysentery and diarrhoea in 1933 was 46,697 with a death rate of 0.9 against 39,562 deaths with a death rate of 0.8 per mille in 1932. The death rate thus increased by 12.5 per cent against the previous year rate as well as the last quinquennium average (0.8). Twenty-four thousand three hundred and nine males and 22,388 females died from these causes. Taken separately, dysentery accounted for 25,980 and diarrhoea 20,717 deaths in 1933 against 21,539 and 18,023, respectively, in 1932; the corresponding ratios were 0.5 and 0.4 against 0.4 in each in 1932. Dysentery and diarrhoea accounted for 3.9 per cent of the total provincial mortality against 3.8 per cent in 1932.

Respiratory diseases

Respiratory diseases were responsible for 82,173 deaths in 1933 with a death rate of 1.6 per mille against 62,249 deaths with a death rate of 1.2 per mille in 1932, showing an increase of 19,924 deaths or 33.3 per cent. The death was higher by 45.4 per cent than the provincial quinquennium average.

Pneumonia

Pneumonia has kept up a steady rise since 1923 and was responsible for 9,179 additional deaths compared with 1932 figures. The total number of provincial deaths from pneumonia in 1933 was 37,337 with a death rate of 0.75 against 0.56 per mille in 1932. The death rates showed increase both in the rural and the urban areas as well as in Calcutta by 41.7, 3.6 and 14.3 per cent, respectively.

Phthisis

Deaths reported from phthisis numbered 14,802 in the province in 1933 showing an increase of 3,001 against the previous year. The increase was shared to the extent of 2,583 by the rural areas and 418 by the towns, of which Calcutta was responsible for 315. The provincial death rate from phthisis showed an increase of 30.4 per cent. The increase in the rural areas and towns was by 33.3 and 13.0 per cent, respectively, while that in Calcutta was by 14.2 per cent. 70.6 per cent of the phthisis deaths in all towns occurred in Calcutta. Eleven towns reported death rates above the provincial urban average (1.0). Eighty-six towns returned rates between 1.0 and 0.1 inclusive per mille. Pabna recorded the lowest rate (0.04 per mille). No death from this cause was reported from 20 towns.

Fairs and festivals

During 1933, no case of infectious disease was reported from any fair in the Burdwan, Rajshahi and Chittagong Divisions. A few cases of cholera occurred at the Nangalbundh mela in the Dacca district. Ganga Sagar mela in the 24-Parganas district was free from infectious diseases except two imported cases of smallpox.

Anopheles ludlowi

Ludlowi menace to Calcutta.—It has been stated in the previous years' reports how the discovery of *A. ludlowi* with a natural infection rate of 23.8 per cent in the jute mill areas at Budge-Budge in October 1930 led to careful investigation into the matter by the specially sanctioned staff for the purpose and how, as the result of this investigation, *A. ludlowi* was found to be breeding not only in several spots on the outskirts of the city but also within the municipal limits of Calcutta. The timely action taken by Government, with whom the Corporation of Calcutta and several other bodies concerned subsequently co-operated, has averted an outbreak of malaria which might have been disastrous to the port and the city of Calcutta. The 'ludlowi' survey and the control work was continued in 1933 as energetically as before. In 1933, this species of anopheles was detected in the fish ponds of the villages situated on the western border of the salt lake and close to the fringe of Calcutta. On the northern border, the village Kalikapur was also affected. In February 1933, Chingrighata was infested and at about the same time breeding places of the species were detected in the Nebugola area of the Calcutta Corporation. In March to May breeding places of *A. ludlowi* were found scattered over Calcutta in an area within half a mile from the western border of the salt lake. In July, an outbreak of malaria took place at Nebugola within the limits of the Calcutta Corporation and also its adjoining areas, and *A. ludlowi* was found to be responsible for the outbreak. In August to October breeding places were detected at Golaghat and in the Lansdowne jute mills and also within the limits of Calcutta between Maniktala and Narikeldanga. In November and December the Bellaghata and Shambazar canals were found to be breeding *A. ludlowi*. On the southern border of the salt lake, villages near the railway station of Garia were also found to be infested. On the banks of the Hooghly, in addition to the previously affected places, the following new places were found infested with *A. ludlowi*, viz, Fuleswar, Bauria (adult *A. ludlowi* was found in 1930), Belur, Dakshineswar and Mankundu. Adults only were caught from Mayapur, Pijuli and Telinipara. As in the previous year, adults were caught from the trains at the railway stations of Majerhat, Howrah and Shambazar and stations in the Canning area and Hasnabad area were found infested.

In January 1933, the attention of the Calcutta Corporation was drawn, at a meeting, by the Bengal Public Health Department to the important development in the salt lake area and asked for their co-operation to prevent *ludlowi* invasion into Calcutta. The Bengal Public Health Department with only one unit of survey and control had to face the danger. Later, when an epidemic of malaria actually broke out at the Nebugola, Chingrighata and their adjoining areas, the Corporation offered a contribution. Major Covell's recommendations for augmenting the special staff were then given effect to. The new units, however, could not be put to work before the middle of July 1933, but an epidemic of malaria on the eastern limit of Calcutta had already started. Since then, the Bengal Public Health Department has been carrying on both the survey and the control work in the salt lake area and only the survey in the areas within the Calcutta Corporation from Ultadanga to Chingrighata, where the mosquito brigade of the Corporation carry on control measures.

Antimalaria scheme for rural areas with quinine and plasmochin.—In April 1933, an antimalaria experiment with quinine and plasmochin was taken up for certain selected areas in the Burdwan district. This area comprises 97 villages with a population of 21,400, of which 30 per cent are children. The spleen index in this tract varied from 60 to 80 per cent. The scheme provided for a course of treatment with quinine to the whole of the population inhabiting the area during the months of April, May and June. Along with quinine treatment, plasmochin was given in daily doses of

0.02 gramme in the case of adults and proportionately less in the case of children for three consecutive days to kill the gametocytes in the system. From July onwards, 30 malaria treatment centres were opened for the area. Six doctors were placed in charge of each group of 5 centres which were visited in rotation. Malaria cases were treated with quinine and plasmochin.

The argument in support of this scheme is that malaria increases in geometrical progression during the period from July to October; this provides favourable conditions for mosquitoes to multiply and for parasites to develop in them. From November, such conditions do not continue. The height of the seasonal peak will, therefore, depend on the initial number of infected cases and the length of the favourable period. If, for instance, 30 per cent infected persons, i.e., in the month of June, can give rise to 50 per cent sickness rate in November in five months' time, then a 20 per cent initial rate will cause a proportionately lesser rise

during the same period. Now, if the initial number of cases can be reduced by treatment in June, the virulence of the seasonal epidemic would most probably be reduced. The centres have been opened to test the efficacy of control on these principles and also to provide early treatment of malaria cases, so as to prevent, as far as practicable, diffusion of malaria by infected mosquitoes.

The intensity of malaria during the malaria season in the area under experiment was far less than that in the surrounding areas. Compared with the previous years, malaria incidence in the same area is reported to have undergone a decrease. The success of the scheme will depend upon the number of people coming under this treatment and on the efficiency of quinine in the cure of malaria. A large proportion of the population inhabiting the area are loath to come under this treatment. The Santals refuse allopathic treatment.

BASAL METABOLISM OF INDIANS IN HEALTH AND DISEASE: ITS CLINICAL SIGNIFICANCE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the November issue (1931, page 601) of the *Gazette* there is an article on 'Basal metabolism of Indians' by Dr. J. P. Bose and Mr. U. N. De. In this article (page 610) the writers make the following statement:—

'The majority of workers who have studied metabolism in the tropics are in agreement with the present writers, viz., that there is no essential difference in the basal heat production in people whether living in the tropics or in the cold or temperate zones'.

Reference to modern work on the subject, however, will not tend to support the writers' contention. Of workers in India the writers have referred to the earlier work of Dr. H. N. Mukherjee (1926), of Colonel Sokhey (1927), and of Drs. Krishnan and Vared (1932), but they do not refer to Dr. H. N. Mukherjee's more recent work with myself (1931, *Indian Journ. Med. Res.*, XVIII, 807) nor to that of Professors Mason and Benedict (1931, *Indian Journ. Med. Res.*, XIX, 75) and of Dr. Banerjee (1931, *Indian Journ. Med. Res.*, XIX, 229).

All of these publications in India show a lower basal metabolism of Indian subjects. Of the publications abroad the writers only refer to five or six papers in their own support, but they do not refer to the large number of recent publications which do not support them.

The writers have referred to the work of Turner (1926) in their support but may I be permitted to draw their attention to Turner's more recent work (Turner and Aboushadid, 1930, *Amer. Journ. Physiol.*, XCII, 189) in which definitely low basal metabolism of Syrian subjects is reported.

I may also mention that the Aub and Dubois' standards are nowadays considered to be about 5.0 per cent too high even for Europeans. So it may appear from Dr. Bose and Mr. De's article that the basal metabolism of their Indian subjects is really 5.0 per cent higher than that of Europeans.

Yours, etc.,
P. C. GUPTA, M.Sc.

BIOCHEMICAL DEPARTMENT,
CARMICHAEL MEDICAL COLLEGE,
CALCUTTA,
8th July, 1935.

[Note.—It is not always necessary, or even possible or advisable, to refer to all the published work on a subject about which one is writing. In this case our contributors were not propounding a theory regarding

basal metabolism in Indians but were reporting their own findings. They state quite clearly that in their experience with Indians the normal basal metabolic rate is about the same as that of healthy Europeans living in temperate climates. From the last paragraph of this letter we gather that even in temperate climates experts differ, but it is not a serious matter if they differ only within the limits of \pm 5 per cent.—EMTON, I. M. G.]

RELIGION AND DISEASE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Reading through the medical papers from India, one finds that reports on cases usually start as follows:—'A. B., Hindu male', or 'C. D., Mohammedan female, etc.' It would appear from these reports that next to one's name the most important fact was one's religion. Medical contributors, some of them very eminent and entitled to the greatest respect, often refer to their patients as 'Hindu male', 'Mohammedan male', etc., though there is absolutely no necessity for so doing. For instance, in the last number of the *Indian Medical Gazette* the following references occur:—Hindu male (malignant tumour), Hindu male (snake bite), Hindu male (melanoma), Mohammedan, aged 35 (bleeding). In fact, in any of the issues of Indian medical papers one sees the same thing.

I believe India is the only country where its medical men refer to their patients by religion. Do we hear in Europe or America of 'Church of England male' or 'Atheist female'? It would be ridiculous; so is our case in India. No wonder that India is the laughing stock of the world as regards its cleavage into religious sections. We, educated citizens of the country, are helping, instead of ending, this division by giving undue and unnecessary prominence to the religious persuasion of our patients.

If the writers desire to give the nationality of their patients it is only necessary to refer to foreign patients, e.g., Chinese. Otherwise, by inference, it follows that the patient is an Indian. In case, as in reports on metabolic diseases, the religion is given as indicating habits of diet, it is better to say 'A. B., aged 35, vegetarian' as the case may be.

I am sure those who think about it will find how ridiculous the whole thing is and they will be wondering how this habit has persisted so long. Through the columns of your paper I would like to appeal to all medical journalists and contributors, especially Indians, to drop this habit of mentioning their patients' religion in their reports and thus to help in the great cause which should be at the heart of every well-wisher of

India, namely, the abolition of communal feeling, through lessening of its prominence.

Yours, etc.,
A. D. SAGAYAM.

NADI,
FIJI ISLANDS.

[To us this is a new point of view, as we think it will be to many of our readers, but nevertheless we see much sound common sense in our correspondent's argument, and we are very pleased to publish his letter.—EDITOR, I. M. G.]

THE RATE OF DEVELOPMENT OF HOOKWORM EGGS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to the article on 'The Rate of Development of Hookworm Eggs' by P. A. Mapleston, published in your July number, we wish to record a recent experience of our own with the stool of a patient in our laboratory at Sriniketan.

In ordinary smear we noted eggs containing four or more cells and a few with band-like structures bent at the extremities. We thought the latter were probably eggs of *Strongyloides stercoralis*, but Dr. J. C. Chakravarty disagreed and advised us to collect and examine a larger number of eggs from the stool by a concentration method.

A portion of the stool was mixed with 5 c.cm. of 5 per cent acetic acid and 5 c.cm. of ether added; it was thoroughly mixed and centrifuged. A great deal of the debris floated to the top and in the clear fluid at the bottom of the tube very many eggs were found.

We now found eggs in every stage of development from four cells up to the band-like larva we had noted previously, and from one egg a fully developed larva was partly hatched thus clearly indicating that all the eggs were those of hookworms in different stages of development.

We are thus able to confirm the observations of the writer of the article referred to above.

Yours, etc.,
AMAR NATH GHOSH.

SRINIKETAN CLINICAL LABORATORY,
SRINIKETAN,
SURUL, BIRBHUM,
2nd August, 1935.

[Note.—Unfortunately the writer of this letter omits to state how long the stool was passed before it was examined.—EDITOR, I. M. G.]

TEETH AT BIRTH

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In my practice I have come across the following instance of teeth at birth:—

In 1921, one child	with two lower central incisors.
In 1926, " " "	" " "
In 1934, two children	" " "
In 1935, one child with left	" " incisor.

My experience may be of some medico-legal interest.

Yours, etc.,
A. F. W. DA COSTA, F.R.C.S.E.,
D.T.M., L.M.S., V.D.,
Civil Surgeon.

BULDANA.

EVIPAN-SODIUM

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I think the following sufficiently interesting to report:—

A European, male, aged 23, six feet, weighing over 12-stone, slenderly but athletically built, was suffering from an ischio-rectal abscess. I decided to give him Evipan-Sodium. The Evipan-Sodium was taken from a box of five ampoules, one of which had already been used. The Evipan was mixed as directed with the

distilled water supplied in ampoules and the solution was injected into the median basilic. Before injection was commenced the patient was told to count, which he did at the rate of 60 per minute. Injection was started with the counting, and given approximately, at the prescribed rate. As no signs of anaesthesia were noted the rate of injection was slowed down so that when the patient had counted up to 160, eight cubic centimetres had been given or about 0.8 grammes. As I considered it unwise to go on, the injection was discontinued. The only thing either I or my colleague noticed was dilatation of the pupils, while the only thing the patient noticed was a slight pain in the arm. Not the slightest evidence of anaesthesia could be detected. I may add that the only other ampoule used out of the box was given the previous week to a coolie and he was completely unconscious when two cubic centimetres of the solution had been given.

Yours, etc.,
HUGH FLACK, M.B.

BEESAKOPIE,
DOOM DOOMA,

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL E. W. C. BRADFIELD, C.I.E., O.B.E., V.H.S., Officiating Surgeon-General with the Government of Bombay, is confirmed in that appointment, with effect from the 14th August, 1935.

Lieutenant-Colonel N. S. Sodhi, M.C., Officiating Inspector-General of Civil Hospitals, Burma, is confirmed in that appointment, with effect from the 12th August, 1935.

Lieutenant-Colonel P. S. Mills, Officiating Inspector-General of Civil Hospitals, Bihar and Orissa, is confirmed in that appointment, with effect from the 21st August, 1935.

On termination of his appointment as Officiating Deputy Director-General, Indian Medical Service, the services of Lieutenant-Colonel F. A. Barker, O.B.E., will be placed at the disposal of the Home Department, with effect from the 24th August, 1935.

Lieutenant-Colonel J. C. De, on return from leave *ex-India*, is appointed as Superintendent of the Campbell Medical School and Hospital, *vice* Lieutenant-Colonel N. C. Kapur, granted leave.

The services of Major G. H. Fitzgerald are placed permanently at the disposal of the Government of the United Provinces, with effect from the 26th June, 1932.

Major W. E. R. Dimond, Assistant Director of Public Health, North-West Frontier Province, is appointed to officiate as Inspector-General of Civil Hospitals and Prisons, North-West Frontier Province, in addition to his own duties, with effect from the 3rd July, 1935 (afternoon), until further orders.

Major W. D. B. Read, an officer of the Medical Research Department, on foreign service under the Indian Research Fund Association, is appointed to officiate as Assistant Director, Central Research Institute, Kasauli, *vice* Captain M. L. Ahuja, granted leave.

The services of Major J. R. Katariya, Superintendent, Presidency Jail, are replaced at the disposal of the Government of India, Army Department, for military duty on the expiry of the leave granted to him under Government notification.

The services of Captain R. D. MacRae are placed temporarily at the disposal of the Chief Commissioner, Coorg, for appointment as Civil Surgeon, Coorg, *vice* Captain Sheridan, I.M.S., granted leave, with effect from the date on which he takes charge of his duties.

Captain D. MacDonald Fraser is appointed to officiate as an Agency Surgeon and is posted as Civil Surgeon, Quetta, with effect from the afternoon of the 13th June, 1935.

The services of Captain M. R. Sinclair, O.B.E., are placed temporarily at the disposal of the Government of the United Provinces, with effect from the 26th June, 1935.

Captain B. S. Sandhu is appointed to act as Superintendent of the Presidency Jail, with effect from the 1st September, 1935, or from the date on which he actually takes over charge, vice Major J. R. Katariya, granted leave.

Captain K. S. Fitch, Civil Surgeon, Midnapore, is appointed as Second Resident Medical Officer, Presidency General Hospital, Calcutta, vice Dr. W. A. Browne.

Captain E. G. Montgomery, Civil Surgeon, Murshidabad, is on relief appointed as Civil Surgeon, Midnapore, vice Captain K. S. Fitch.

The probationary appointments of the under-mentioned officers are confirmed:—

Captains

1. W. J. Virgin (Tor).
2. J. Brebner.
3. H. W. G. Stannton
4. J. D. Gray.
5. D. W. Taylor.
6. P. H. Addison.
7. J. W. D. Goddall.
8. F. J. Doherty.
9. S. G. O'Neill
10. C. B. Miller.
11. M. G. Leane.
12. G. E. S. Stewart.
13. D. P. Dewe.

The following appointments are made:—

Temporary Commission (I. M. S.). To be Lieutenant
Abdul Aziz Khan, dated 12th June, 1935.

To be Lieutenants (on probation)

24th June, 1935

Coleman Kevin Byrnes (seconded).

Raymond Joseph Henderson.

John Revans (seconded).

Charles Walter Alban Searle, 26th June, 1935.

LEAVE

Colonel C. I. Brierley, C.I.E., Inspector-General of Civil Hospitals and Prisons, North-West Frontier Province, is granted leave for 7 months and 29 days, with effect from the 3rd July, 1935 (afternoon), preparatory to retirement.

Lieutenant-Colonel F. J. Anderson, Professor of Clinical Surgery, Medical College, Calcutta, is granted leave for 5 months, with effect from the 24th May, 1935.

Previous notification is hereby cancelled.

Lieutenant-Colonel N. C. Kapur, Superintendent, Campbell Medical School and Hospital, Calcutta, is granted leave for 1 year, with effect from the 4th September, 1935, or from the date of relief.

Lieutenant-Colonel R. V. Martin, Superintendent, Yeravda Central Prison, is granted leave for 4 months and 12 days, from the 9th November, 1935, or the date of relief.

Major J. R. Katariya, Superintendent, Presidency Jail, is allowed leave for 2 months and 17 days, with effect from the 1st September, 1935, or any subsequent date on which he may be relieved.

Captain A. M. Sheridan, Civil Surgeon, Coorg, is granted leave for 2 months and 25 days, combined with furlough, out of India, for 3 months and 5 days and study leave for 6 months, with effect from the 1st September, 1935, or any subsequent date of availing.

Captain M. L. Ahuja, Officiating Assistant Director, Central Research Institute, Kasauli, is granted leave for 1 year, with effect from the 1st September, 1935, or any subsequent date on which he may avail himself of it.

PROMOTIONS

Major to be Lieutenant-Colonel

R. A. Warters. Dated the 12th July, 1935.

Captains to be Majors (provisional)

Dated 8th July, 1935

G. P. E. Bowers.

J. S. Riddle.

J. E. Gray.

Dated 24th July, 1935

S. Smythe.

Dated 27th July, 1935

M. H. Wace.

Lieutenant to be Captain

P. W. Whiteman. Dated 27th June, 1934, with seniority from 1st May, 1934.

Lieutenant (on probation) to be Captain (on probation)

G. P. Charlewood. Dated 27th May, 1935, with seniority from 17th December, 1934.

RETIREMENTS

Colonel H. E. Stanger-Leathes, R.A.S. Dated 6th August, 1935.

Lieutenant-Colonel K. G. Gharpurey. Dated 28th July, 1935.

Notes

THE BOYLE-DAVIS GAG

By V. S. HARIHARAN, M.B., F.R.C.S. (Eng.)

The Boyle-Davis gag used in operations on the oropharynx, such as tonsillectomy, consists mainly of a fixed gag with a movable and replaceable tongue depressor below and a tooth plate above. This upper tooth plate consists of two flattened hooks into which sit the upper row of teeth; so much so when the gag is in action and the mouth is opened wide the upper tooth plate takes pressure from the upper row of teeth. These flattened hooks are small and shallow, and do not fit properly in all cases, with the result that the gag often slips at a critical moment and a great deal of anxiety to the surgeon is caused. To avoid this slipping of the gag Messrs. Down Brothers, London,

have been kind enough to make for me according to my specification the following modification in the gag as in the figure.

The two hooks of the upper tooth plate are replaced by a single one centrally placed half an inch broad and an inch and a half long and curved up so as to take pressure from the hard palate and not from the upper row of teeth as is ordinarily the case. This keeps the

gag steady and there is very little chance of its slipping, nor does it produce any abrasion of the hard palate at the site of the pressure, because of the smooth curve given to the plate.

I have done a number of operations with this modified gag and have not had any single case where the gag has slipped. I believe the surgeon can have more confidence in this modified gag than in the original one.

TWIN FORCEPS

By A. WYNN GREEN

TWIN forceps to be used in the resection or resection advancement operation on the internal rectus in order to avoid the employment of calipers and rulers have been made for me by Messrs. Down Brothers, Limited.

These forceps are really two Prince's forceps united together in such a way that one slides on the other and is readily detachable.

Twin forceps.

The forceps have a ten millimetre scale, D, by which can be made an exact measurement of the length of muscle to be removed. They are applied in the manner of ordinary Prince's forceps—both forceps being clipped to the muscle. The upper forceps B is then opened, and moved down the scale. The muscle is now secured between the jaws of forceps B; when the muscle between A and B has been cut away, forceps A is removed, and the operation is completed in the usual way.

ARE CHILDREN CORRECTLY FED?

NEW LIGHT ON GROWTH OF CHILDREN IN SUMMER

SPEAKING at the Annual General Meeting of Virol Limited, Mr. A. E. Canney, Managing Director, said that considerable discussion had recently taken place in the medical press on the subject of malnutrition during the age of growth. He pointed out that *malnutrition* in this respect was, perhaps, an unfortunate word, since the layman understood it to arise from insufficiency of the total quantity of food consumed, whereas all the evidence indicated that the main factor was lack of balance in the diet.

It had been suggested that this lack of balance could be corrected by administering concentrated preparations of vitamins; but recent experiments had shown that this procedure gave no beneficial results. The correct method of attacking the problem of malnutrition was shown by the results of important investigations published in *The Medical Officer*, 30th March and 6th April, 1935.

RECENT CONFIRMATION OF THE VALUE OF VIROL

In these investigations a number of children, all receiving an ordinary home diet, were divided into four groups. One group was given no special treatment, and the other three received respectively cod-liver oil, halibut-liver oil, or Virol. Those receiving halibut-liver oil were also given sufficient milk to provide calories equivalent to the other supplements.

The groups were interchanged at intervals in such a way that at the end of the experiment each child had been on every treatment in turn. It was thus possible to compare the effects of the supplements on the growth-rate of children in a scientific test which eliminated individual differences in the children themselves.

In the result, it was found that cod-liver oil, and halibut-liver oil with milk, each showed some improvement, but not up to standard. In sharp contrast, the

growth-rate produced by Virol was not merely better than that of the other supplements, but actually attained the figure usually accepted as ideal. This was direct proof that Virol was in itself adequate to restore normal growth and health to malnourished children. This implied that the deficiencies of their ordinary diet had been completely restored—a result extremely difficult for parents to achieve in any other way.

VIROL TO REPLACE EXTRA WASTE OF ENERGY IN SUMMER

A further point arising out of the investigation referred to was the influence of the summer period on the children's growth-rate. During this period all the children lost weight, with the exception of those receiving Virol. The advent of summer time and long hours of daylight implied on the one hand a loss of sleep and appetite, and on the other hand, greatly increased opportunity for exercise and expenditure of energy generally. It was obvious that loss in weight

must occur unless steps were taken to counterbalance this expenditure. The significant point was that the other supplements accomplished nothing in this direction, whereas the use of Virol resulted in the children's weight being maintained.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE DISORDERS OF DIGESTION

THE COMMONER DIGESTIVE DISORDERS OF CHILDREN IN INDIA

By E. H. VERE HODGE, M.D. (Cantab.),
M.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Medicine, First Physician, Medical College
Hospital, Calcutta

PREFACE

Few infants pass the whole of their infancy without some mild attack of abdominal pain of a transient character. This pain is known as colic and is caused by spasm of the intestine or the accumulation of wind. The cause is usually a mild indigestion due to errors or excess of food, hasty feeding, or, in the case of breast-fed infants, some indiscretion on the part of the mother, which has rendered the milk indigestible. Simple colic is of short duration and easily amenable to treatment. No purgative, such as castor oil, should be given while there is pain. Should severe pain persist for more than an hour in spite of appropriate treatment, the development of organic disease within the abdomen must be suspected.

Treatment.—Gentle massage of the abdomen followed by hot applications—a carminative mixture such as the following: Sodium bicarbonate 2 grains, aromatic spirits of ammonia 2 minims, spirits of chloroform one minim, and peppermint water to one drachm.

When there is much wind and the abdomen is full, a number 8 catheter, well-lubricated, may be passed for an inch up the rectum and left in position for half an hour or so.

When the urgent symptoms have subsided we must consider the cause; if there is constipation we give a rectal washout followed by one teaspoonful of castor oil, for a child of one year; if there are signs such as vomiting or undigested particles in the stools we cut down and adjust the diet to the standard diet for the infant's. In the case of breast-fed infants the administration of water before the feeds may improve the digestion.

During infancy and childhood the digestive tract is not attuned to the strain constantly thrown upon it by injudicious feeding and other hygienic faults, so that we commonly find, in the occurrence of digestive disturbances, evidence that our management is not all that it should be.

General considerations

The commonest disorders are:—(1) Constipation, (2) Diarrhoea, (3) Dyspepsia (infantile intestinal dyspepsia).

CONSTIPATION

This is particularly prevalent in India and is in all probability to some extent to be traced to the poor mineral content of the food, together with the want of an invigorating quality in the climate, excessive loss of fluid through the skin, lack of roughage, lack of fat, lack of vitamins, and general inertia. The symptoms associated with chronic constipation are many; they are:—

Appearance—complexion sallow, dark rings under the eyes, a brownish staining of the skin folds, particularly in the arm-pits and in the groin, abdomen prominent, breath apt to be foul, and tongue coated.

Nervous system—irritability, restlessness and sleeplessness or marked restlessness during sleep with tendency to night starts.

Other symptoms—irregular temperature at times, lack of energy, occasional attacks of colic or vomiting, and capricious appetite. Not infrequently a few drops of blood may be passed at the end of a hard stool, owing to the rupture of a small vein. Such an accident need not cause alarm.

Regularity in the daily passage of stools may be misleading. There may be an incomplete clearance of the bowel; some of the faeces is passed while the remainder accumulates in the bowel, a process known as hoarding. When this is suspected a bowel wash may be given and the result may reveal that a large quantity of faeces has accumulated within the bowel. Further, stools may be passed regularly but still be delayed; the stool passed should have passed twenty-four hours earlier. This may be suspected when the stools are hard, dark and streaked with brownish-mucus are attached to them. The general condition of the child will also rouse this suspicion.

In infants at the breast, constipation is common, especially during the first two months of life. The child is otherwise in good health, but the motions are infrequent and hard. It is at this time important to take steps to correct this condition, lest habit be established. The mother by correcting her diet, eating more fruit and vegetables and taking plenty of water, may bring about a natural cure, but it is useless for her to take laxatives with the vague idea that these may affect the child. The amount of food taken by the child must be checked by weighing the child before and after feeds as the constipation may be due to insufficient food or even lack of water. One teaspoonful of milk of magnesia added to the bottle is an excellent corrective and in addition a teaspoonful of liquid paraffin may be given daily.

In all cases of obstinate constipation dating from birth, and particularly in those cases where there is much straining at stool, examination should be made of the anus to exclude one condition, spasm of the sphincter, which is not an uncommon cause of early constipation and which, if uncorrected, will lead to considerable

trouble later. The little finger well covered with vaseline is gently introduced. Where there is spasm, considerable resistance will be felt, which must not be overcome by undue force but by gentle pressure maintained until the resistance is felt to give way. This process is repeated daily for a week. Some cases of this nature are of an extreme type, the abdomen becomes distended, the child is blue from pressure of the distended bowel on the lungs, and is constantly screaming, particularly after the meals, when the pressure within the abdomen is further raised. Relief may be given immediately by the simple manoeuvre described above, followed by a small olive-oil enema.

In dealing with constipation in bottle-fed babies, the first step will be to revise the food, to ensure that the quantity is sufficient, that the amount of fluid is sufficient, and that the constituents are in correct proportion. The fault is likely to lie in high proteid with low fat and carbohydrate; we may therefore dilute our milk and add a little extra fat in the form of top-milk, artificial cream, or a teaspoonful of cod-liver oil to two or three bottles, and increase carbohydrate in the form of milk sugar or Mellin's food. Failing this we may employ milk of magnesia. The prolonged use of suppositories or enemata is not to be encouraged.

After the age of six months, constipation may be more obstinate and stronger laxatives may be required. In such cases we must carefully examine the abdomen for signs of any marked dilatation of the colon, as in the event of such signs being present, treatment by laxatives and dieting must be supplemented by massage and oil or saline enemata. In simple cases, as a laxative, we may use five drops of liquid extract of cascara combined with 30 drops of syrup of figs, to which may be added one drop of tincture of podophyllin if the stools are putty-like.

For older children it must be distinctly understood that the only merit in laxatives or purgatives is that they are given with the one idea of setting up a regular habit; if need be, they may be continued for a month, until the tone of the bowel is restored and a habit established. A child should be taught to go to the closet regularly at a fixed time daily and this routine, if persisted in, will be of life-long benefit. There are many useful laxatives for this purpose, e.g., aromatic extract of cascara ($\mathfrak{m} x$), liquid extract of liquorice ($\mathfrak{m} x$), and syrup of figs (3i or more).

The writer has found the following prescription effective :—

℞
 Extracti cascarae aromatici .. \mathfrak{m} 15
 Syrupi ficorum \mathfrak{m} 45
 Paraffini liquidi 3i
 Decoctum chondri crispi ad 3ii

Two to four teaspoonfuls according to age.

A useful home remedy for constipation is the following :—

℞

1 pound of French plums,
 1 pound of Demerara sugar,
 1½ ounces of pounded senna,
 ½ ounce of ground ginger.

Stew the plums in a little water until tender, remove the stones, then add the rest, mix, and beat into a paste.

Give one teaspoonful at night for a child of four.

The subject of constipation has been discussed at length partly because of its importance later to the child's welfare and partly because of its frequency in this country, but, before concluding, it is necessary to remember that laxatives are but a small portion of the treatment. A regular habit must be aided by a regular and proper diet. In the tropics, fluid readily leaves the body by the sweat glands. The child therefore should drink copiously and, when he so desires, between meals; the diet should be simple with the avoidance of seasoned or hot dishes, pastry and sweets should be allowed only in moderation, and fruit and vegetables should be taken freely. Oranges and papaya are usually readily procurable at any time and may be given.

In our experience, those cases which are sufficiently severe to be brought to a doctor are never cured by a so-called 'suitable diet' alone; there is always some fault, either in the intestinal musculature or the secretory function of the bowels, which needs correction. Indeed, some of these cases complicated by wasting and lack of appetite abundantly prove the recent researches on the importance of the endocrine glands, for we have seen cases persisting despite drug, diet and massage treatment, which have rapidly been cured by giving small doses of thyroid extract.

In this country, a not uncommon type of constipation met with is that following dysentery. We think these cases are best treated by the lubricant, liquid paraffin in teaspoonful doses, and, if this fails, 5 to 10 drops of the cascara evacuant, or other preparation of this nature, may be added to the paraffin.

ACUTE DIARRHOEA

In all forms of ill health in childhood, whether primarily in connection with the digestive tract or not, the earliest reaction is apt to be diarrhoea. The disorder shows the widest variations in gravity, from the simple acute attack due to overfeeding or chill to the most severe forms which endanger life. All cases, however, must be treated promptly and the cause sought.

The main causes are errors of diet whether habitual or single, climatic conditions, contamination or infection of food, and dysentery, or the condition may be incidental to acute illness.

Classification

1. Simple, dietetic or climatic.—Failure to regulate the diet according to climatic conditions is responsible for most cases. In some cases all the elements of the diet may be in excess, but more commonly the fat or carbohydrate is in excess, or there may be irregularity in feeding with sweets or biscuits between meals. The onset of digestive derangement in children is characteristically sudden. This is often misleading as the mother will attribute it to some immediate cause, such as a feed of soured milk, whereas careful scrutiny will reveal the fact that the child has not been well for some time, that is to say, the digestion has been failing gradually and the onset of the diarrhoea possibly with vomiting is merely the culmination.

2. Catarrhal diarrhoea.—In this condition there is an actual superficial inflammation of some part or the whole of the alimentary tract, which may be secondary to the simple form, but is more commonly produced by bacterial contamination of the food. This group tends to be severe and resistant to treatment, and includes such conditions as that usually known in Great Britain as summer diarrhoea (acute diarrhoea and vomiting of infants), and the acute fulminating form of white diarrhoea known as cholera infantum.

3. Infective diarrhoea.—A condition caused by the infection of the bowel with certain specific organisms.

4. Dysentery.

5. Parenteral diarrhoea.—The diarrhoea which sometimes accompanies generalized diseases or acute disease outside the alimentary tract, e.g., at the onset of measles, during pneumonia, or with acute disease of the ear.

SIMPLE OR DYSEPTIC DIARRHOEA

This form does not as a rule present very serious symptoms. The child has no appetite, the stools are frequent, green and sometimes frothy with excess of liquid and are apt to be passed explosively. Sometimes there is vomiting and often there is fever, though not of a high degree. When the fat has been much in excess the stools will be very pale and greasy looking. With excess of starch, the abdomen is distended, the stools are frothy and there is much passage of wind. Diarrhoea due to proteid indigestion is less common; here the stool is greenish or brown surrounding tough yellowish lumps of curd. The stools of the first two varieties tend to be acid and this acidity combined with the frequency leads to a reddening and soreness round the anus.

CATARRHAL OR INFECTIVE DIARRHOEA

In the more severe types with persistent vomiting, the stools are excessively frequent and brownish at first. Very soon the stools contain little solid matter and consist mainly of a greenish fluid with abundant mucus and often

with streaks of blood. The child suffers from pain and there is crying and straining before and after the stool. In addition, the constitutional symptoms grow rapidly more severe, and are attributable to two causes, the toxæmia of bacterial contamination and dehydration, that is, the excessive drainage of fluid from the tissues. The child appears shrunk, the face is pinched, the eyes sunken, and a greyish coloration appears round the mouth. In young infants the fontanelle may be felt to be depressed. The hands and feet become cold and bluish. There is marked restlessness and lack of sleep from constant pain or discomfort, and the cry becomes enfeebled to a mere moaning. At the inception the temperature will be high, even as much as 105° to 106°F. , but as collapse sets in the temperature drops and may become dangerously low. Sometimes the surface temperature is subnormal while the temperature taken in the rectum is high. Nervous symptoms, twitchings, convulsions, loss of consciousness, and retraction of the head are prominent. One peculiar and serious sign is seen in the later stages, that is the eyes become markedly congested, with profuse lachrymation. The urine is diminished or may be entirely suppressed.

In the most severe type, known as cholera infantum, the stools are white resembling rice-water, and constantly drain away. Vomiting is severe and the progress of the disease is appalling in its rapidity.

TREATMENT

Mild cases—simple diarrhoea.—All food is stopped for twelve hours or more, but water is given freely, if necessary sweetened with a little saccharin. The first feeds are of whey or albumin water in amounts half the size of the usual feed according to age and given somewhat frequently, say at intervals of $2\frac{1}{2}$ hours. A mild laxative is indicated if there is much undigested matter in the stools, castor oil is safe but apt to cause vomiting, so that a mixture of sodium sulphate—grs. 10, sodium citrate—grs. 5, syrup—minims 10, and water to 2 drachms, is preferable and may be given two-hourly to three or four doses according to the response. If there is much watery purgation, 'Colloidal' kaolin—grs. 10 may be added to each dose. If there is much mucus or frequent small stools containing undigested matter and disturbing the child, a bowel wash of normal saline may be given.

In all cases of diarrhoea, the stools should be carefully examined for traces of yellowish pus, which is an indication of infection of the dysenteric type.

Later, additions to the feed should be made with caution; skimmed milk replaces the whey by degrees and Mellin's food is added. The normal diet is reached by stages according to the tolerance of the child. When the attacks have been severe and the digestive capacity accordingly impaired, the early milk feeds may

with advantage be acidified. Before the child is permitted to return to full diet, the original diet must be scrutinized for errors.

In treating the more severe forms the greatest promptitude is required. There must be no delay as the secret of success lies in limiting the gravity of the disease.

The essential indications, in the order in which they demand attention, are:—

1. To replace early the lost fluid and so prevent a serious degree of dehydration.

2. To control the vomiting so that fluid may be taken by mouth.

3. To get rid of the poison within the bowel (bacteria, toxins, or poisonous food products) and to counteract the toxæmia.

4. To ensure rest and prevent convulsions.

5. Stimulation.

Water may be given by the mouth in a bottle practically continuously if the child will suck, otherwise in a teaspoon. Where there is vomiting, if water cannot be retained then we must have recourse to other methods. It is useless to give rectal saline as it is constantly rejected. It therefore remains to give normal saline fluid under the skin, four ounces being injected slowly by the gravity method every six hours or, when skilled assistance is available, by the intravenous route.

Vomiting may be treated by washing out the stomach with two grains to the ounce of sodium bicarbonate. When the fluid returns clear a further small quantity is run in and left there. The process is exceedingly simple. If the child will swallow, the same effect is attained by giving sodium bicarbonate drinks which will be vomited and so wash out the stomach. Other measures are as follows:—

(a) Fractional doses of calomel—grain 1/12th with milk sugar every half hour up to a total of three powders, or

(b) Atropine sulphate injection—grains 1/1000th to 1/400th, according to the age of the child, repeated four-hourly.

(c) Mustard plaster, of appropriate strength, to epigastrium.—

The following saline mixture can be given every hour, the interval being lengthened as the case progresses:—

R			
Sodii sulphatis	grs. x
Sodii bicarbonatis	grs. v
Glycerini	℥ xv
Aquam	ad 5i

A certain judgment should be used in administering salines, and, if the purgation has already been excessive, it is wiser to add small doses of kaolin—grs. 10, or bismuth carbonate—grs. 5 to the mixture to moderate the flow, but not to stop it entirely and thereby lock up the toxins in the bowel.

The child is constantly disturbed by pain, discomfort and the passage of motions. This

will result in exhaustion to the nervous system and a tendency to convulsions. Accordingly, as soon as the most acute symptoms have passed, it is advisable to give a sedative mixture as follows:—

R			
Phenazone	gr. ½
Potassii bromidi	gr. i
Syrupi	℥ xv
Aquam	ad 5i

Repeat in two hours if necessary, otherwise give four-hourly.

Stimulants may be necessary, the best being brandy, five drops in a teaspoonful of water every three hours. In case of urgency we may inject adrenalin—minims 1 to 3, according to age, and repeat four-hourly.

As soon as the acute stage is over, we must consider the question of feeding. There has been a great loss of protein, carbohydrate and mineral salts, all of which we must replace at the earliest possible moment, bearing in mind the digestive tolerance. For protein, we begin with whey, and for carbohydrate one of the best foods is raisin tea, made by adding one tablespoonful of chopped raisins—(kismis) to a pint of boiling water, cooling and straining; of this one ounce may be given every hour. The feeds should at first be kept small, one to two ounces and given every hour or two hours. Calcium lactate—grs. 2 may be added to three feeds daily.

Further advances are made with extreme caution. The whey is gradually replaced by skimmed milk, or, as an additional precaution, we may peptonize the skimmed milk. A little later we may add Mellin's food and gradually reduce the time of peptonizing the milk. In early convalescence, acidified milk will be found suitable. The return to the normal diet must be gradual.

Drugs, beyond those mentioned above, have no place in the treatment of this condition, and particularly must caution be used in regard to the use of astringents. If used at the wrong moment, they will cause distension and fever, due to the accumulation of intestinal intoxication products. They must be used only when there is evidence that there is a persistent over-activity of the intestinal musculature after inflammation or irritation from undigested food has subsided.

There are certain other complications which require attention.

1. Hyperpyrexia (temperature over 104°F.):—Ice-bag near the head and tepid sponging.

2. Collapse, with coldness of hands and feet and subnormal temperature:—Hot mustard bath, or, better, electric radiant heat, hot-water bottles, brandy by the mouth—five drops two-hourly in one teaspoonful of water, if the child does not swallow rub the gums with undiluted brandy, adrenalin—℥ 2 hourly to four-hourly

or tincture of ephedra— η x-xv six-hourly, and finally subcutaneous saline.

3. Irritation round the anus and in the rectum:—The external irritation of the skin round the anus may be prevented by washing with a dilute solution of sodium bicarbonate, a teaspoonful to a pint of water, and smearing the parts with vaseline, or by an application of zinc oxide—grs. 20 added to an ounce of castor oil. This application is renewed every time the bowels are opened.

For internal irritation, the washing out of the bowel in the early stages has its uses, especially if there is an accumulation of undigested food in the rectum or few motions with much straining, but in the advanced stages of the more acute type it is of little value and even harmful, as the mucus which is formed acts to some extent as a protection.

Threatened convulsions, that is to say, twitching of the hands and rolling of the eyes, may be averted by the timely administration of brandy, or the bromide mixture.

Opium must never be given at the onset of diarrhoea as it will prevent the evacuation of the irritating material. It may sometimes be used during convalescence when the bowel is in a state of hyperactivity, and the food is hurried on without digestion. In such cases a mixture such as the following is advised, for a child of one year old:—

R
Bismuthi carbonatis .. grs. v
Tincturæ camphoris compositæ η ii
Tincturæ belladonnæ .. η jss
Gummi acaciæ .. q. s.
Aquam .. ad 5i
ter in die

Convalescence.—After an attack of severe diarrhoea of any form, the child's general health is much reduced and steps must be taken forthwith to restore it. The digestion is impaired and feeding must be guarded with the greatest caution. There is a particular tendency to obstinate constipation which must be met by suitable aperients, cream of magnesia and liquid paraffin being the best, and by general tonics. There is also often serious anæmia which in more grave cases may be adequately dealt with by the use of liver extract. Iron should also be given in an easily digestible form such as the following prescription:—

R
Syrupi ferri iodidi .. η xx
Extracti malti .. 5 ii
bis in die—post cibum

This, however, must not be given so long as there is any diarrhoea, or until the constipation has been corrected. An excellent remedy is a soup made of liver and spinach, given three times a week. Fresh fruit is introduced early

and the fat-soluble vitamins are replaced by giving Radiostoleum or Adexolin as soon as the digestion will tolerate it. When possible a change of air to the seaside or the hills according to season should be given.

CHRONIC DIARRHOEA

Chronic diarrhoea is a disease which may start in a number of ways; it may follow an acute attack, as the result of ill adjustment of the diet; it may be due to the persistence of an infection, usually of the dysentery group, or to the presence of worms; it may be due to a persistent error in the diet or to intolerance on the part of the child to some article of diet even though given in what to other children would be a correct amount. Further, the diarrhoea may be part of some constitutional disease such as rickets. The disease may start early in life and is more common in artificially-fed infants.

The diarrhoea is not necessarily constant, periods of quiescence, even with constipation, occur. The importance of the condition lies in its effect on the general nutrition of the child. He becomes pale and languid, there is wasting and anæmia, there is also naturally a decreased resistance to other infections, so that the child easily falls a victim to any infectious disease.

Treatment.—This is in the first place dietetic according to the nature of the stools. At the outset the stools should be examined for evidence of worms or of chronic dysenteric infection, either amœbic or bacillary.

When due to carbohydrate indigestion the abdomen is distended, the stools pale-coloured and frothy. When due to fat indigestion, the stools are greasy, white and bulky with intervals during which hard white stools are passed. The condition may be due to faulty digestion of all food factors. We should as far as possible identify the offending factor, as during the stage of building up this factor must be added to the diet with the greatest caution.

Treatment is undertaken in two stages; the first is the stage of rest to the bowel and recovery, and the second, the stage of restoring the impaired nutrition. It is clearly useless to attempt the second stage till the first stage is completed and the digestive functions have to some extent been re-established. Relapse often occurs owing to premature attempts to increase the patient's weight or to the administration of tonics, such as cod-liver oil, before the digestion can tolerate them.

During the first stage the child is kept quiet, free from excitement and with prolonged resting hours. The diet is mainly of whey or peptonized skimmed milk, to which Mellin's food may be given if there is no distension. Clear soup may be given to lend variety and stimulate the appetite, but it has very little food value.

Medicinal.—Start with a mild saline-aperient if there is much undigested food in the stools;

TABLE
Showing the distinction between the acute forms of diarrhoea

I SIMPLE	II CATARRHAL	III INFECTIVE	IV DYSENTERY
<p>Cause— Errors of diet. Excess of food. Climate.</p> <p>Onset— Usually preceded by signs of lack of appetite.</p> <p>Main symptoms— Vomiting early but not persistent, stools frequent, character according to error in feeding.</p> <p><i>Excess of fat</i> Early—greasy. Later—whitish. Greenish, watery with white flecks of fat and mucus, acid in reaction.</p> <p><i>Excess of starchy food</i> Stools—frothy, greyish, much flatus, distension of abdomen, later green stools, acid.</p> <p><i>Excess of protein</i> Stools—greenish with tough lumps, yellowish-white, alkaline. In general, mucus not excessive, no blood, 2 to 20 in number, fever slight, respond easily to starvation.</p>	<p>Arising from simple or 'summer' diarrhoea, from 'turned' or contaminated milk.</p> <p>Sudden.</p> <p>All degrees of severity. Vomiting may be severe and persistent. Stools green, mucus abundant. Blood in severe cases. Constitutional symptoms more marked. Fever constant, sometimes high. Tongue dry and dehydration rapid.</p> <p>Stools 2 to 20 in number.</p> <p>Resistant to treatment.</p> <p>Cholera infantum: a very severe form with intractable vomiting, white stools, early collapse, subnormal temperature.</p>	<p>Contaminated food. Specific infection.</p> <p>Sudden.</p> <p>Acute diarrhoea and vomiting with early collapse. Fever often high falling as collapse sets in. Nervous symptoms marked, convulsions or coma. Tongue dry. Dehydration rapid.</p> <p>Stools 2 to 20 in number.</p> <p>Response to treatment not very satisfactory.</p>	<p>Specific infection.</p> <p>Sudden.</p> <p>Stools contain no faecal matter, much mucus, stained red or pure blood. Characteristic spots of yellowish pus. Odour sour and fishy. Gripping severe.</p> <p>Stools 10 to 80 in number.</p> <p>Early collapse. Fever usual, rapid wasting and dehydration. Exhaustion from sleeplessness. Lung complications common.</p>

Group III tends to merge into group IV. In group III the preponderating appearance of the stools is greenish with much mucus and sometimes blood, but close examination will reveal spots of pus, which may become predominant.

follow this by a powder for a child of a year old, given twice daily for three days:—

R
Magnesii carbonatis .. grs. ii
Tincturæ nucis vomici .. ℥ i
Infusi rhei .. ℥ xx
Infusum gentianæ compositum .. ad 5i

After this the following mixture is given, three times a day before food:—

R
Pulveris hydrargyri cum cretæ .. gr. ¼
Pulveris rhei compositi .. grs. 1½
bis in die

In some cases, owing to persistent overaction of the muscle of the bowel, the diarrhoea will not settle down, in spite of adequate dietetic treatment. In one type, lenteric diarrhoea, the introduction of food into the stomach induces an outburst of activity throughout the intestine, so that each meal is followed by an urgent stool. In

such cases sedatives to the bowel are required and the mixture recommended for the same condition after acute diarrhoea may be given.

During the second stage, or stage of building up, gradual additions to the diet are made, the effect being carefully watched. The chief signs of improvement are the return of the appetite, and the improvement in the colour and consistency of the stools. Constipation may even develop through paucity of roughage in the food and this is a sign for increasing this food constituent.

The first addition is of carbohydrates, preferably in the form of Mellin's food, later unmalted cereals, such as Robinson's patent barley, well-boiled rice or some breakfast food may be added. If there is persistent evidence of carbohydrate indigestion and a tendency to distension, Takadiastase—one tablet—may be given with each meal. Easily fermentable articles, such as potatoes, sweet biscuits and pastry, are to be avoided. Fats, either in the form of full cream

milk, butter or articles fried in fat, are added with great caution, particularly in the hot weather when the fat tolerance is at its lowest. Articles which are liable to irritate the intestine mechanically, such as pips and seeds, are rigidly avoided.

Other measures, the provision for adequate rest, fresh air, sunshine and the prevention of chill, are taken. Finally, once the digestion is functioning, iron tonics and vitamins, as in the convalescent stage of acute diarrhoea, are prescribed.

One form of chronic diarrhoea, happily very rare in this country, must be mentioned. This is celiac disease which is characterized by wasting to an extreme degree of emaciation, stunted growth, a markedly-distended abdomen and the passage of large white stools, over prolonged periods. The treatment of this condition is in its essentials the exclusion of all varieties of food except protein, until the stools regain their normal colour.

DYSENTERY

Bacillary dysentery is a common disease in India and affects children with frequency and severity. Amebic infection, though exceedingly common, rarely takes the form of a typical dysentery in childhood.

Bacillary dysentery may be divided into two groups, the dysenteries proper, due to infection of the bacillus of Shiga or of Flexner, and the para-dysenteries, due to infection with other organisms. The distinction between the infective forms of diarrhoea and the para-dysenteric group is artificial, as the same organisms cause acute infective diarrhoea with green stools and severe toxæmia at one time, and at another diarrhoea of the dysenteric type with pus in the stools. The microscopic examination of almost all stools of the infective type will reveal pus cells, though pus may not be apparent to the naked eye. It is characteristic of all forms of bacillary dysentery that the digestive functions are suspended from the outset, so that for the first few hours the case may suggest acute dyspeptic diarrhoea. It is quite possible that these bacteria which we associate with acute diarrhoea and vomiting may become pathogenic in the presence of dyspepsia which will result in a change of their environment.

True dysentery.—The infection by the bacillus of Shiga is the most severe one on account of the associated intense toxæmia. Occasionally the onset is exceedingly abrupt with high fever, vomiting and diarrhoea and early collapse of such severity as to rouse the suspicion that the case is one of cholera, and to require early intravenous transfusion of saline solution to counteract the severe and sudden dehydration. The Flexner type is more common but usually less severe, with less toxæmia and general constitutional disorder.

Symptoms common to both forms.—Onset sudden with pain and griping; frequent loose motions which are at first brown and watery and later assume a characteristic form, i.e., they are small and are passed with straining, contain no faecal matter, have a fishy odour quite different from that of the normal stool, and are of great frequency, sometimes as many as 80 a day. In the milder cases they consist of mucus tinged pink, but in the more severe cases they consist almost entirely of pus with shreds of membrane; occasionally pure blood is passed.

General symptoms.—The abdomen is tender to the touch, there is marked restlessness and exhaustion from sleeplessness due to the constant straining at stool, the temperature is as a rule raised, and there is a rapid pulse. Owing to the number of stools there is a tendency to dehydration. The appetite is at first lost but later is apt to be ravenous. In the milder cases the disease runs a course resembling a severe diarrhoea, often with green stools and much mucus, and only close inspection of the stool will reveal spots or flakes of pus. Convalescence is slow on account of the severe impairment to digestion and there is a tendency for the persistence of a lack of tone in the bowel and frequent constipation.

Treatment.—This may be divided under four headings:—

(1) *Specific treatment.* Antidysenteric serum is divalent, that is to say, effective both against Shiga and Flexner infections. It is advisable, therefore, once we have established the diagnosis of severe dysentery, to wait no longer for laboratory confirmation, but to administer the serum. Dosage—5 to 10 c.cm. to a child one year old, repeated after twelve hours, if necessary. The serum must be given within the first forty-eight hours of the disease, otherwise serious harm may ensue. Of recent years bacteriophage has been introduced which has been of the greatest value. In the more severe cases one ampoule should be given every two hours, preceded by water containing a small pinch of sodium bicarbonate, till five have been given in the twenty-four hours. During the bacteriophage treatment food should as far as possible be withheld, or, at the least, the bacteriophage be given on an empty stomach.

(2) *Relief of discomfort and sleeplessness.* While it is undesirable to give astringents which will lock up the toxic materials, we may with advantage control the excessive activity of the bowel, with the colic and straining, by the administration of belladonna. We may further induce quietness and sleep by giving bromides. Opiates in any form should not be given. Further, so long as the bowels are opened freely, we may give small doses of bismuth which will have a soothing effect and form to some degree a protective covering to the ulcerated surfaces.

(3) Drainage. In order to induce a free watery flow from the bowel, magnesium sulphate in doses of 20 grains to one drachm, according to the age of the child, dissolved in water, is given two-hourly daily until a free flow is insured.

(4) Prevention of dehydration. Water must be given freely. As in the majority of cases there is no vomiting, this is a matter of no great difficulty though in the acute fulminating Shiga type it may be necessary to give intravenous saline.

Diet

The patient is best kept on water only, for the first twenty-four hours at least. After this the diet will depend upon the type of infection. For the Shiga type, as the organism flourishes best on albuminous media, the feeding should consist entirely of carbohydrate, glucose, or Mellin's food made with water. In the Flexner type, on the contrary, carbohydrate should be avoided and the patient fed on whey and later on peptonized skimmed milk. One must increase the diet to normal very gradually, bearing in mind that the digestion is seriously impaired.

For the para-dysenteric group, the treatment is much the same, save that the ordinary specific treatment is of no avail. In such cases of recent times the specific bacteriophage produced by the Calcutta School of Tropical Medicine has proved of great value.

AMŒBIC DYSENTERY

The characteristic symptoms of amœbic dysentery as seen in the adult are rarely seen in young children. Occasionally we meet with cases where the stools are definitely of the dysenteric type though different from those of bacillary dysentery. Faecal matter is present and is of a typical dark reddish-brown colour with which is intimately mixed blood and mucus. The number is usually comparatively small, four or five daily. The abdomen is tender, particularly in the lower part of both sides. There is little or no fever. More usual is a chronic infection of the same organism which leads to obstinate diarrhoea with greyish stools and periodic intervals of obstinate constipation, loss of appetite and weight, vague abdominal pains and progressive anæmia.

Diagnosis in such cases is suggested by the persistent tenderness in the abdomen, sometimes the colon may be felt to be thickened, and this is confirmed by the presence of living amœba or cysts in the stools. One examination is insufficient to exclude the disease and it may be necessary to examine as many as six times after the administration of a non-oily aperient. Not infrequently there is high fever in these cases owing to the escape of *Bacillus coli* from the bowel into the circulation.

Treatment. The patient is put on a soft easily-digested diet of milk, Mellin's food and

a clear soup, and the bowels are kept freely open by small doses of saline aperients, preferably magnesium sulphate. Emetine is a specific in such cases, but children are intolerant and suffer from depression or even collapse if the dose is excessive. For a child of one year the dose must not exceed $1/15$ th of a grain, at four years it should be not more than $1/8$ th, and in both instances the dosage should be limited to six injections. Further treatment is carried out with a view to eradicating the infection, a procedure which may be exceedingly difficult. Carbarsone in doses appropriate to age, 0.075 gramme to a child of four, may follow the emetine treatment. Though this drug is an arsenical preparation it has been given with absolute impunity in a large number of cases, the only adverse manifestation being pains in the abdomen if the bowels are allowed to become constipated. The course of carbarsone is limited to ten days and should not be repeated for three months.

One other protozoal parasite, *Giardia intestinalis*, has been found to produce a chronic diarrhoea with mucus or occasionally a little pus in the stools. The diagnosis is made by the discovery of the living organisms or cysts in the stools. Treatment is by Stovarsol. Dose gr. $\frac{1}{2}$ daily for a child of one year for six days.

INTESTINAL DYSPEPSIA

(Mucus disease or Eustace Smith's disease)

Chronic intestinal dyspepsia is one of the commonest causes of ill health among children in India and is entirely due to errors in the diet, the main error being the preponderance of starchy or sugary food. In European children the general digestive tolerance is lowered in the hot weather at which time the disease usually starts, and improvement is immediately seen on transfer to the hills or to Europe. Not infrequently the predisposing cause is one of the infectious diseases of childhood whereby the general vigour is lowered. The disease lies midway between chronic constipation and chronic diarrhoea and partakes of the character of both.

The symptoms noted by the mother are often those referable to the general nervous system rather than to indigestion. Restlessness at night, night terrors, irritability and teeth grinding are common so that when there is any change in the demeanour of the child or any unusual nervous symptom our first point of investigation is the digestion.

Other symptoms to be noted are, want of energy, actual loss or failure to gain weight, irregularity of the bowels—sometimes diarrhoea and sometimes constipation, and persistent cough due to gastric irritability. It is somewhat misleading that the child does not often complain of pain. The tongue is furred or pale, flabby and glazed, there is sometimes irregular fever and the appetite is capricious. The motions are often slimy, hence the name mucus disease, and

they may contain much indigested matter or may be frothy and large. As a variety there may be the urgent passage of stools immediately after meals, a condition known as lenteric diarrhoea. Associated with this condition we sometimes meet with persistent bed wetting. The general appearance of the child is somewhat characteristic, the complexion is muddy and unhealthy looking, and the face may appear puffy with dark rings under the eyes. He is thin with a marked prominence of the abdomen due to distension. This distension is sometimes so marked that the lower ribs are pushed outwards or the muscles of the abdomen are separated, so that when the child in the supine position lifts his head there is a marked bulging down the centre of the abdomen. When there is much constipation the folds of the skin, as in chronic constipation, will be stained. The treatment is mainly dietetic and is based upon the fact that all the functions of the digestive system are impaired but mainly those of carbohydrate and fat digestion. In many cases the disease is prolonged or accentuated by the administration of tonics, particularly cod-liver oil, before they can be tolerated. During the first stage the diet is limited to skimmed milk with Mellin's food with soup, beef tea or chicken soup and malted rusks such as Allenbury's. With improvement we advance to the second stage and add baked bread, a little honey, fruit juices, boiled fish, minced chicken or mutton and selected vegetables, such as cauliflower or very young mashed carrots. Later, the fish may be grilled instead of boiled and small varieties in the diet are permitted by the addition of such articles as 'Force', Madeira-cake, a very little butter and fruit juice. The third stage consists of the gradual return to the ordinary diet appropriate to the age. There are some articles which must be avoided for a considerable time, notably all articles containing pips, seeds or indigestible husks, such as pineapple, strawberry jam or coarse oatmeal, salt meats, bananas, smoked fish, and whole milk.

Drug treatment.—Rhubarb and grey powders for three days followed by the rhubarb mixture. Where there is much persistent carbohydrate indigestion, as evidenced by much distension of the abdomen, one Takadiastase tablet may be crushed over each meal. Later a tonic such as the following may be given :—

R	Syrupi ferri iodidi	5js
Q	Extracti malti	5ijs
	b.i.d., p.c.			

Sunshine and fresh air are essential and where available ultra-violet rays will do much to improve the general tone.

Additional factors :—(a) As in all cases of digestive disturbance in children who have developed their teeth, special attention must be

TUBERCULOSIS OF THE MAMMARY GLAND

By AMAR NATH GOYLE, M.B., Ph.D.

K. G. KRISHNASWAMY, M.A., B.S.

and

A. VASUDEVAN, M.B., B.S.

(From the Department of Pathology, Medical College, Madras)

A REVIEW of the literature of diseases of the breast shows that tuberculosis of this tissue is of infrequent occurrence. Since Sir Astley Cooper described the condition in 1829, about 200 cases have been reported up to the year 1926. Since then some more cases have been described and to these we add a report of three cases from the files of the General Hospital, Madras.

Report of cases

Case I. Clinical history.—R., Hindu female, aged 18 years, was admitted for pain in the left axilla and left breast on 18th November, 1932. She had recurrent attacks of fever and cough for the last eight months. Three months before coming to the hospital she noticed a lump in her left axilla which broke down discharging pus for a week. The discharge reappeared 10 days prior to admission to the hospital. Two days before her admission, she noticed a swelling on the left side of the left breast.

On local examination, there was a sinus in the left axilla extending 3 inches deep from the skin, discharging a whitish thick fluid. Adjacent to the sinus, there was a hard tender mass. The breast below the nipple was tender and warm to the touch.

X-rays showed enlarged glands in the hilum of the left lung, heart displaced to the right, infiltration around the right hilum, and opacity of the right apex. The right supra-clavicular glands were enlarged, and the right cardio-diaphragmatic angle was encroached upon.

Naked-eye appearances.—Externally, about 2 cm. below and to the left of the nipple is seen a circular

(Continued from previous column)

paid to their condition and any decay must be rectified, as frequently digestive disturbances arise owing to lack of mastication of the food; this failure of mastication is due to the tenderness of decayed teeth. Some children are habitual bolters, they do not chew their food at all; this is a matter for education. (b) In all cases of this type we must remember the possibility of infection by worms and when possible stool examination should be carried out. (c) Give water freely, but allow no food or sweets between meals. (d) Allow no food to be eaten after 6-30 p.m., except a cup of milk and a rusk. (e) If possible allow no water at meals, but give freely one hour before or one hour after. (f) Do not give too much milk in addition to a substantial dietary.

Acknowledgments.—I am indebted to Professor M. N. De and to Dr. Profulla Das Gupta for their liberal assistance and practical suggestions in the foregoing article. The article will subsequently appear in the eighth edition of Birch's *Management of Children in India*.

DIFFICULTIES IN THE BACTERIOLOGICAL DIAGNOSIS OF CHOLERA VIBRIOS*

By S. C. SEAL, M.B.

(Bacteriologist, Cholera Carrier Enquiry, Indian Research Fund Association, All-India Institute of Hygiene and Public Health, Calcutta)

THE identification of *Vibrio cholerae* sometimes presents extreme difficulties. This is why, in spite of the many attempts of a large number of workers during the course of the last half a century to solve this problem of identification,

* Being a paper read before the Scientific Section of the Calcutta Medical College Centenary on the 30th January, 1935.

(Continued from previous page)

How familiar we all are with cases of sniffing noses, others again that have intermittent attacks of congestion, sometimes one nostril closed, sometimes the other; others complaining of hay fever unable to face dust or pollen, really cases of pseudo hay fever, and not the rare kind which are sensitive to certain substances. All these are cases of badly ventilated noses, and why treatment by desensitizing vaccines fails in many instances is because the distinction has not been drawn between an ill-ventilated nose and one suffering from a true sensitivity to pollen, etc. All these cases call for conditioning, as the first step in any treatment. It happens sometimes that a first conditioning fails to produce a cure, the manipulations should be repeated again and as they are not severe the patient is, as a rule, agreeable to submit as he has had some benefit. Remember that the condition of nose blockage is a very worrying one and the sufferer is willing to go through a lot for relief. It is the establishment of a free airway that is the object in view, and one manipulation may not be sufficient to effect this; the septum has to be persuaded to remain in a new position; it is just the upper and back part which is the offender and is scarcely accessible for a submucous resection. In a few noses there is a bulge of the outer wall high and near the roof, as well as a septum deviation meeting it, making things difficult, and if the surgeon can crack one or the other he is lucky. If you embark on a policy of conditioning noses, you will find them. If I have been able to find them to be so numerous in a country district, they must be in hundreds everywhere. It is simple enough after some experience, and you will earn the gratitude of many, who will come back and describe to you how fresh and cold the air feels passing through the airway you have opened up. Of course it is not all plain sailing, there is perhaps a chronically-inflamed mucous membrane to treat after the conditioning, but it is in a much better position for improvement.

controversy still exists regarding the differentiation of true cholera from cholera-like vibrios recovered from various sources. Only the bacteriological diagnosis will be considered here.

During an epidemic of cholera the bacteriological diagnosis is usually made by simple microscopical and cultural examinations, supplemented, if necessary, by the cholera-red reaction and agglutination tests. But during the non-epidemic periods, or at the beginning of an epidemic when there has been no actual incidence of clinical cholera, a diagnosis is difficult to make even when all the tests have been performed, especially in view of the recent studies which have shown that the non-agglutinable form of the vibrio can produce acute clinical cholera and that this form has been recovered from many fatal cholera cases.

The true identity and significance of vibrios isolated from the 'carriers' of cholera, or cholera 'contacts', and from the non-human sources, such as water, milk, food, flies, sewers, drains, etc., are often very difficult to ascertain and the investigations have to be performed with utmost care. Vibrios found under these conditions often bear such an extremely close resemblance to true cholera vibrios that they can hardly be differentiated from them without an elaborate study consisting of: (a) morphological character, (b) cultural character, (c) biochemical tests, (d) serological tests, (e) animal experiments, and (f) 'phage' lysability. The essential characters by which collectively the vibrio cholera species may be readily distinguished from the other members of the genus are motility, single terminal flagellum, aerobic growth, cholera-red reaction, funnel-shaped liquefaction of gelatin, absence of phosphorescence and pigment formation in peptone-water culture, pathogenicity to laboratory animals by intraperitoneal and intravenous injections, low virulence for pigeons by intramuscular injection and the specific serological reaction with the homologous antiserum. Each one of the characters taken separately has been found to exhibit great variation, so that not only do difficulties in identification arise but there is also a possibility of missing a vibrio during its primary isolation.

The variations mainly noticed during our experimental works may be briefly summarized under the following headings:

(A) Morphological characters (plate XIV, figures 1 to 5)

Appearance.—Apart from the variations of the degree of apparent curvatures, relatively straight organisms have been found. Some strains exhibit very short, thick cocco-bacillary forms; others are elongated and filamentous; there are again others which, to all intents and purposes, resemble bacilli. Recently, an almost coccoid form of vibrio has been isolated from an acute case of cholera.

Morphological characteristics of cholera vibrios (approximate magnification = $\times 600$).

Fig. 1.—Typical *Vibrio cholerae*.

Fig. 2.—Filamentous and spirillar forms of *V. cholerae*.

Fig. 3.—Bacillary form of *V. cholerae*.

Fig. 4.—Coccoid form of *V. cholerae*.

Fig. 5.—Pleomorphic forms of *V. cholerae*.

In old cultures, however, distorted, highly atypical, and various involution forms have been noticed, e.g., straight organisms, thick swollen individuals, long spirals, spherical forms with faintly-stained centres, pear-shaped and beaded organisms and individuals which present a completely distorted structure. No budding or branching forms have been found, as reported by some workers.

Motility.—The organisms are usually highly motile with 'scintillating' and 'centrifuge' movements, but sluggishly motile forms are not uncommon, and a non-motile variety has also been noticed, in some rare instances, in type cultures of vibrios associated mostly with the changes in colony appearances.

Flagellum.—*Vibrio cholerae* has usually a single polar flagellum to which the movement is supposed to be due. The presence of two flagella, one at each pole or two at one pole, has been occasionally found in single or a group of individuals of the variants, old cultures and some of our recently isolated carrier strains. Multiple flagella have been described by some workers but doubted, except perhaps in the case of *V. massuah* which belongs to the so-called 'paracholera' group.

(B) Cultural characters

Colony appearances.—Colonies of cholera vibrios on alkaline nutrient agar (24 hours' growth) are generally smooth, circular, 1 to 2 mm. in diameter, moist, translucent with a faintly bluish tint gradually becoming brownish on continued incubation. But many fluctuating variations have been noticed both in our primary isolations and in subcultures, e.g., rough dry colonies which undergo spontaneous agglutination in normal saline, opaque colonies with irregular surface, adherent and difficult to emulsify, ring colonies with an opaque centre and transparent border, small tiny colonies (plate XV, figure 6) like those of streptococcus and similar to those described by Gildemeister (1922) as 'dwarf' colonies, and others showing varying mixtures of roughness and smoothness both in appearance and by Millon's test.

(C) Biochemical properties

Proteolytic effects.—One of the chief characteristics of *V. cholerae* is its marked proteolytic action, as exemplified by the liquefaction of gelatin and coagulated serum. These effects are well marked in the recently-isolated cultures with a little variation in the rapidity of liquefaction. But we have many of our collected strains showing poor or completely negative proteolytic effects. There are some which produce proteolysis of coagulated serum but not of gelatin, or *vice versa*. Many of the dissociant forms, however, show completely negative results, while some of the long-cultivated smooth vibrio strains show partial or complete loss of proteolytic effects.

Indol formation.—The nitroso-indol reaction or the cholera-red reaction has been noticed with great constancy, but is in no way the specific effect of cholera vibrio. On the other hand, certain vibrios have been isolated from cholera cases, in which it is absent. The rough variants and some of the carrier strains very often show negative results.

Saccharolytic effects.—The common fermented carbohydrates without production of gas are: glucose, maltose, saccharose, starch and dextrin; various other sugars and carbohydrates are also decomposed by different strains, but these reactions have not served to distinguish *V. cholerae* from the allied species. Lactose is not usually fermented by *V. cholerae*, but late fermentation has been observed in many cases. Some of the carrier strains, studied recently, ferment lactose early, within 24 to 48 hours. Mannite is fermented by most of the strains, but sometimes recently-isolated strains ferment it slowly and some older strains may fail to ferment it altogether. Again some carrier strains have been obtained which do not ferment saccharose. Salicin has been found to be fermented by some strains, specially the variants. It has been found that arabinose is fermented both by a very small percentage of *V. cholerae* and occasionally by the non-agglutinable strains and therefore it cannot be used as a 'test' sugar as claimed by Heiberg (1934). With certain strains there may be acid formation in milk after 3 to 7 days and few strains only have shown a marked acid change and coagulation. Wherry (1904) and others also claim that acid formation in and coagulation of milk are distinct properties of certain strains. These saccharolytic effects have, however, been found to change or vary during the course of laboratory subculture (this is probably associated with the variability of the organisms themselves). A dissociant of a typical smooth cholera vibrio has been obtained, which ferments glucose only with difficulty.

Hæmolytic effects.—Since the observations of Kraus and others it has been held that true cholera vibrios grown on rabbit or sheep blood-agar are usually non-hæmolytic, in contradistinction to some atypical and 'paracholera' vibrios which are actively hæmolytic.

The isolation of six actively hæmolytic strains at El Tor by Gotschlich in 1905 brought the question of hæmolytic action into particular prominence. The strains differed from true cholera vibrio mainly in their production of active hæmolysin, and were declared by Gotschlich and others to be not true cholera vibrios. This evidence of hæmolytic property as a criterion for differentiating non-cholera from cholera vibrios aroused considerable interest as well as a certain amount of controversy; but some of the subsequent workers have claimed that true cholera vibrio may exhibit undoubted hæmolytic effects. According to

van Loghem (1913) and later Greig (1914) and Kovács (1926), the hæmolysis that is observed in cases of true cholera vibrios is a 'hæmodigestion', and not true hæmolysis—a property of the El Tor and some 'para-cholera' strains which produce active 'hæmotoxin' (an exotoxin) that lyses blood with the production of oxy-hæmoglobin, as tested by spectroscopic examination.

We have isolated both hæmolytic and non-hæmolytic agglutinable strains of vibrios from cholera cases, convalescents and carriers. Non-agglutinable vibrios are more hæmolytic, but many strains of agglutinable vibrios have been found to lyse human and not sheep's corpuscles. From a study of more than 400 strains of vibrios Pasricha (1934) concludes that the hæmolytic property of a strain is an extremely variable one and can disappear under laboratory conditions. No correlation between the hæmolytic property and toxicity has been noted.

The variability of the hæmolytic power has been attributed by some to phage contamination, while others consider that the reaction towards the blood is a fairly stable property among the vibrios, being unaltered by lysis with bacteriophage or passage through animals, but the hæmolysin to human blood is thermolabile and is destroyed by heat at 65° to 70°C. within an hour (Zimmermann, 1934). Kolle and Prigge (Kolle, Kraus, Uhlenhuth, 1928), on the other hand, suggest that the hæmolytic action or its absence may be the functions of biological variation and not a stable character.

On the whole, it may be said that the hæmolytic property of vibrios is a variable one and cannot be employed with impunity for the differentiation of vibrio groups.

(D) Serological tests

There are two main types of antibody reaction—antibacterial and antitoxic of which the former is clearly demonstrable in cholera.

Agglutination.—This test has been thought to be highly specific. The serum of a rabbit immunized by a true cholera vibrio and having a titre as high as 1:25,000 will undoubtedly pick out the same type of cholera vibrios from cholera-like and other vibrios. These cholera-like organisms again are highly agglutinated by their own high-titre sera which do not agglutinate the true cholera vibrios. Though the transitional or intermediate forms have not been established it is not possible to say that the inagglutinable vibrios are not true cholera vibrios.

Absorption test and cross-agglutination.—Besides the homologous agglutination, pseudo- and para-agglutinations have been described, but the absorption test of Castellani (1902), designed to distinguish between the group or co-agglutinins and primary or specific agglutinins, has been a real advancement in the

serological tests. We have always found it useful in difficult cases of inagglutinable or partially agglutinable vibrios, and by this method we have been able to corroborate our results obtained by simple agglutination test and compare the serological behaviour with the antigenic structure.

Variability of agglutination.—We have found that by cultivation in the laboratory many of the non-agglutinable forms have acquired agglutinability. From about 40,000 stools of pilgrims at Mecca, examined by Doorenbos (1934), in over five years, only non-agglutinable vibrios were obtained but these, he observes, after one or two transfers on agar have shown properties of agglutinable strains. The occurrence of temporarily inagglutinable forms is particularly observed during the ascending phase of the cholera epidemic and more markedly during its decline. The agglutinable form, on the other hand, is almost universally obtained during the height of the epidemic. Again, persistent and repeated examinations of stools of the healthy carriers, undertaken recently, have revealed that some of them are passing non-agglutinable vibrios at certain times and the agglutinable ones at others. These so-called non-agglutinable forms are not only found in the stools of cholera patients, convalescents and carriers in conjunction with or without the agglutinable variety, but also in waters of wells, rivers, village tanks, sewers and drains.

Influence of seasons, climate, etc., on agglutinability.—The influence of seasons, climatic conditions, temperature, humidity and rainfall on the agglutinability and other characters of vibrios are undoubtedly important factors in the epidemiology of cholera and should be studied.

There is a greater tendency for the vibrios to acquire agglutinability during the winter months in which the agglutinable form has not only been recovered from the actual cholera cases but also from many of the waters of the village tanks and from some of the healthy carriers who had been previously passing the non-agglutinable variety. This preliminary observation, if substantiated, may have a great significance in the natural life cycle of cholera vibrios (with special reference to Lower Bengal).

The technique of agglutination.—The success of the agglutination test not only depends upon its specificity, but also on the methods employed, and on the type of the agglutinogens used, whether H (flagellar) or O (somatic). The application of temperature of 100°C. for two hours to a suspension of cholera vibrios has little or no effect on the agglutinability of the suspension by the cholera antiserum; the O or somatic antigen is highly thermostable, in contradistinction to H or flagellar antigen which is destroyed easily by heat above 60°C. for a few minutes.

The usual type of agglutination reaction done for the identification of cholera vibrios is the flagellar agglutination, but this has also been found to vary according to the different methods employed. For example, some advocate plain suspension in normal saline, some in 0.1 per cent formalized saline, others 0.1 per cent formal-treated 24 hours' broth culture, and so on. It has been recently observed by us (Linton and Seal, 1935) that usually better results are obtained by using living suspensions of 18 to 24 hours' growth on agar in normal saline. Some of the vibrios previously labelled as non-agglutinable have been found by this method to agglutinate with cholera antiserum at a titre as high as 1:1,000 and in one case 1:2,000.

The other factor which is also to be considered is what standard agglutinating serum is being used for the test. The same organisms tested against Madsen, Cantacuzene, Kasanli, Shullong and our own sera often give different results.

Compared to II agglutination better results have been obtained with O agglutination, in our experience, and it is tentatively suggested that this would be a more reliable serological method for the diagnosis of cholera vibrios. The use of pure O antigen would therefore be the best means of preparing the diagnostic antiserum, which, according to our recent experiments, is better tested against the living emulsions.

Another factor which may occasionally lead to some difficulties is the 'zone phenomenon'—a long-recognized common source of error in the interpretation of the results of agglutination tests with organisms in general.

Effect of bacteriophage on the mutability of agglutination.—When a bacteriophage-lysed broth culture or agar-plate culture of vibrio is allowed a further period of incubation, sometimes turbidity appears in the broth and colonies on the agar plate. These are called 'secondary cultures' resistant to bacteriophage. Antigenic changes have often been noticed in these secondary cultures. The appearance of a larger percentage of non-agglutinable vibrios towards the declining phase of an epidemic has been attributed by some to this phage action.

Pasricha, DeMonte and Gupta (1931) observe that a certain percentage (20 per cent of the series tested) of the non-agglutinable cholera-like water vibrios are lysable by cholera phage. Some of the secondary cultures recovered after phage action have been found to be still agglutinated by the antiserum prepared from the parent strains and some by the specific cholera antiserum, thus bringing the latter group into a close serological relationship with *V. cholerae*. From this observation it has been suggested that, in endemic centres, many of the serologically different vibrios are but mutant forms of true cholera vibrios and that these may change into the potential cholera-genic vibrios under the influence of bacteriophage.

Some workers, however, consider that bacteriophage is the essential cause of the variation in agglutination reaction as well as in some of the biochemical and cultural characters of certain vibrios; but such variations have been observed not only as an effect of bacteriophage but also in cultures uncontaminated by phage. It is therefore an open question as to what the significance of these changes may be in the natural history of *V. cholerae*; for the variations produced by bacteriophage have only been possible in our laboratory experiments and it has not yet been absolutely proved that such changes do also occur in nature or inside the human system.

Serological variants.—From the culture of the same specimen of stool of a clinical case of cholera, vibrios have often been obtained which resemble each other in all the characters of a true vibrio except in their serological behaviour, one group reacting and the other not reacting to the specific high-titre serum. Again, there is a greater tendency to find non-agglutinable vibrios or less-agglutinable ones during convalescence and the declining phase of epidemics. Now it is to be determined whether this inagglutinability is due to an alteration in an originally agglutinable vibrio or to an apparent alteration due to the increasing preponderance of inagglutinable cholera vibrios originally present in small numbers, or whether they are to be regarded as non-cholera vibrios having no causal connection with the disease.

The change of originally agglutinable vibrios to inagglutinable forms has been attributed to one of the following factors, (1) symbiosis with other intestinal organisms, (2) growth under increasing immunity in the body and (3) phage action. There are, of course, many authentic cases of cholera in which no bacteriophage could be recovered all throughout the course although the vibrio isolated was non-agglutinable on all occasions; some of these cases ended fatally.

Dissociants and their characters.—Literature on the subject of transformation of the agglutinable to non-agglutinable forms, although still meagre, is gradually increasing and coming into prominence. The change from agglutinable to non-agglutinable forms has been very easy. Organisms derived from a single colony have been found to dissociate into the smooth- and rough-colony forms during the ordinary course of subculture or by the application of various special methods, such as ageing of cultures, growing on phenol-agar, treating with bacteriophage, and cultivating in media containing specific immune serum or high concentration of salt or peptone water, etc. Such dissociated rough forms have been found to lose virulence, agglutinability and some biochemical and cultural characteristics. The change from non-agglutinable to agglutinable forms has also been obtained but mostly with greater difficulty.

Recently, Linton, Mitra and Seal (1935) have obtained much better dissociants from a highly agglutinating 'Rangoon smooth' (plate XV, figure 7) cholera vibrio. One 'Rangoon rough (1)' (plate XV, figure 8) shows moderately rough colonies and reacts barely at 1:200 with 'Rangoon smooth' high-titre (1:12,800) anti-serum, but otherwise resembles its parent strain. The other—'Rangoon rough (2)' (plate XV, figure 9)—shows extremely rough 'medusa-head' colonies, differing from its parent strain and 'Rangoon rough (1)' in practically all its characters. It is not agglutinated at all by the 'Rangoon smooth', 'Rangoon rough (1)' or other anticholera sera. An antiserum, prepared from this non-agglutinable dissociant, agglutinates its homologous strain at 1:25,000, but fails to agglutinate not only its parent strain and 'Rangoon rough (1)' but also most of the other strains tested. Antiserum prepared from 'Rangoon rough (1)', on the other hand, agglutinates its parent strain at 1:200. The above results have been confirmed by absorption and cross-agglutination tests. Thus strains, which, if found in nature, would have been considered unrelated to cholera, have been derived from a typical agglutinating cholera vibrio.

From this variant, again, Linton and the author of the note have, on two different occasions, been able to recover, by special methods, a smooth colony—'Rangoon smooth (recovered)' (plate XV, figure 10)—which resembles the parent strain almost in every respect and agglutinates at 1:6,400 with the previously mentioned 'Rangoon smooth' antiserum. Studies are still in progress to find out whether it has also regained its chemical antigenic structure. At Kasauli also, an originally non-agglutinating and poorly-protective water vibrio has been, during a period of six months' bi-weekly subculture, transformed into an agglutinating highly-protective form resembling a smooth agglutinating cholera vibrio.

The above observations may probably be taken as some evidence in favour of the view that the weakly-agglutinable or inagglutinable vibrios recovered from clinical cases of cholera, cholera convalescents and carriers may be true cholera vibrios. Persons harbouring such vibrios should undoubtedly be regarded as suspects. Instances are not rare in which a possible connection has been noted between clinical cholera cases and healthy carriers passing non-agglutinable vibrios.

Other serological tests

Bacteriolysis (Pfeiffer's reaction), a combination of agglutination and bacteriolysis, the complement-fixation, and the precipitin reactions have been found to correspond closely to the agglutination reaction and are hence attended by similar drawbacks.

Correlation of agglutinability with other characters

The correlation with other serological tests has already been noted, but each one of these tests including the agglutination reaction is but confirmatory to others and none is a final one.

Hæmolytic power and pathogenicity have not been found to correspond with the serological tests. For example, some non-agglutinable vibrios may sometimes be virulent inasmuch as they can produce fatal cholera in man. Smooth and rough forms, on the other hand, may serve to demonstrate a connection with virulence as a character of the vibrio.

Serological reactions in identification

Amongst all the tests by which cholera vibrios are identified a positive serological test is undoubtedly necessary to make the diagnosis absolute, but a negative serum test, as has been shown above, does not immediately exclude the possibility of the organism being a true cholera vibrio. The following account will further illustrate the difficulties in strictly adhering to the agglutination reaction as a diagnostic test: Two strains of vibrios (nos. 20 and 67) isolated from the Mecca pilgrims in 1930, giving positive Pfeiffer's reaction and partial agglutination, were sent to five different laboratories for identification. Out of these five, one laboratory declared both of them as non-agglutinating non-cholera vibrios and one diagnosed no. 67 only as belonging to the latter variety. This variation of the reports from different laboratories may either be due to a variation in the agglutinating sera or more possibly to the actual differences in the strains themselves, that is, depending upon just what colony has been picked up for study and upon the varying constitution of the organism composing it.

(E) Animal experiments

The test of pathogenicity of vibrios into guinea-pigs and pigeons and protection experiments in animals are the last of the series of methods commonly employed for the identification of vibrios. But as man alone amongst the animals is susceptible to cholera, and cholera-like vibrios being more pathogenic to experimental animals, no great reliance can be placed on the results of animal experiments except as a confirmatory test.

(F) Phage lysability

Study regarding the bacteriophage is yet far from complete. New phages are still being discovered and added to an already long list (A to H, K and L and many others). Different vibrios have been found to behave differently with these phages. They may be lysable by one or more of these phages or may be completely resistant to all. 'A'-phage lysability has been held as a criterion for complete smoothness, but smooth vibrios have later on been found by

Colony characters of *V. cholera* and its dissociants (approximate magnification = $\times 40$).

Fig. 6—Small streptococcus-like colonies ('dwarf' colonies).

Fig. 7.—Rangoon smooth colonies

Fig. 8—Rangoon rough (1) colonies.

Fig. 9—Rangoon rough (2) colonies

Fig. 10.—Rangoon smooth (recovered) colonies.

Pasricha and his collaborators (1932), which are not A-phage lysable. The difficulty specially arises with those vibrios which are phage resistant. Non-agglutinable vibrios obtained from cholera cases, convalescents, carriers, water, etc., have often been found phage resistant or lysable only by few or mixed phages. On the whole, phage lysis may be utilized as an additional confirmatory test, and this is always done nowadays in all experimental work. Attempts are also being made by the workers on cholera phage to classify vibrios according to their lysability by different phages.

Carrier vibrios

Vibrios isolated from healthy carriers are mostly non-agglutinable but resemble *V. cholera* in many respects. In our recent studies contrary to the previous findings, we have also obtained agglutinable vibrios from some of these carriers.

Perhaps it would also be worth while to test the sera of these contacts and carriers for any agglutination reaction with the vibrios isolated from such individuals, as well as with other known agglutinating and non-agglutinating cholera or cholera-like vibrios, with a view to ascertaining any possible interrelationship between the carriers and the cases.

Conclusion

The position as regards the so-called atypical forms of cholera vibrios is still unsettled. In a disease that is considered to be water-borne, the problem of the extracorporeal existence of cholera vibrios, e.g. in water, is as important as that of human carriers, and so demands very careful attention and further research. Inagglutinable vibrios will probably in future have to be included in the aetiological factors of cholera and be tested with special sera. Also, in the light of recent observations in serological analysis the whole subject of agglutinability should be revised and the statements of the older authors accepted with reservation.

In view of the above facts, either we must get an ideal anticholera serum, sufficiently broad antigenically to include all possible types of vibrios associated with the production of cholera, or we must classify the vibrios into different definite types, as has been done with the pneumococci and the meningococci and, after finding out their interrelationship to each other, prepare type-specific antiserum from each one of them to be used for final identification, or, using our present resources, test the organisms against the various standard agglutinating sera available, e.g., Madsen, Chittenden, Koser, Shillong, and pure-line antisera corresponding to S-, O-, R-, A-phage-lysable strains and to some typical non-agglutinable vibrios.

Also, the convalescent sera showing some titre with the organisms isolated from the stools of the persons affected might be utilized for the

identification of vibrios; in this way it may be possible to show that an isolated cholera-like vibrio, reacting with the convalescent serum, is the true cause of choleraic affections, if not a true cholera vibrio itself.

The attempts at serological and other classification have so far not been successful, as they have been beset with many difficulties which will not probably be overcome until some systematic interrelationship amongst the vibrio groups is found out; and on this will depend the preparation of better diagnostic high-titre sera, a better understanding of the carrier and epidemiological problems and of the position of the so-called cholera-like and water vibrios, and the proper selection of the strains for the preparation of potent anticholera vaccines, sera, etc.

Recently, however, an extensive study of the interrelationship of the whole vibrio group and of the chemical changes which accompany dissociations has been taken up by Linton and his co-workers including the writer. Their basis of grouping is on the actual constituents of which the vibrios are built up, and apparently stands on a better principle. Out of the vibrio strains collected from the different parts of the world, they have isolated two proteins and three polysaccharides, tentatively allowing six groups to be built up combining in each case one protein and one carbohydrate. The special interest of this classification lies in the fact that it not only reveals the interrelationship of the vibrio groups but also suggests a basis for their variations. The relationship of the serological behaviour to the chemical antigenic structure with its changes underlying dissociations is simultaneously being worked out.

My best thanks are due to Dr. R. W. Linton, ph., Officer in charge of the Cholera Inquiry under the Indian Research Fund Association, and to Lieut.-Col. A. D. Stewart, C.I.E., I.M.S., Director, All-India Institute of Hygiene and Public Health, Calcutta, for their kind help and permission for reading and publishing this short note.

THE USE OF STRAMONIUM FOR THE RIGIDITY AND DROWSINESS FOLLOWING ENCEPHALITIS LETHARGICA

By H. STOTT, M.D., F.R.C.P., D.P.H.
LIEUTENANT-COLONEL, I.M.S.

Physician to King George's Hospital, Lucknow

THE use of stramonium in post-encephalitic conditions, especially for Parkinsonian rigidity and mental apathy, has not received the attention it deserves from the medical profession. With a daily dose of stramonium the patient's life may be rendered comparatively happy. With it, he may be enabled to accomplish the fundamental necessities of life, to walk, dress and feed himself, to write and even to earn his own living. Without it, the patient may be compelled to drag out a crippled and sleepy existence with his daily wants falling as a burden on others. The stramonium must be given continuously in large doses, *e.g.*, half-a-drachm of the tincture thrice daily. At the West Park Mental Hospital, London, many cases of post-encephalitic Parkinsonism are cared for. Most of these patients are kept on substantial doses of the stramonium tincture for many years. If the stramonium be withheld it is found that the patients rapidly relapse to their former pitiable condition. Stramonium is also in common and satisfactory use throughout the British mental and general hospitals.

The history of introduction of stramonium is of interest. In 1895, Erb discovered the calming effect of hyoscine injections for the tremors of paralysis agitans (senile Parkinsonism). About 1914, Dr. Arthur Hurst noted that larger doses of hyoscine could be given with greater benefit and the toxic effects which would otherwise ensue prevented by adding pilocarpine to the hyoscine injections.

When it was found that the Parkinsonian syndrome frequently followed encephalitis lethargica, it was only natural that hyoscine should be tried in this condition also. Quite unexpectedly however hyoscine was found to have little or no effect on the tremor which is

generally much less pronounced than in senile paralysis agitans, but on the other hand was found to exert a very favourable influence on the rigidity following encephalitis lethargica, whereas the rigidity of paralysis agitans remains completely unaffected by hyoscine. In 1926, stramonium was found even more effective than hyoscine in relieving rigidity, slow movement and salivation. The mental, as well as the physical, condition of the patient was also profoundly affected. In 1928, Hurst suggested prescribing pilocarpine with larger doses of stramonium to avoid overdose symptoms of dry mouth, vomiting, and of accommodation paralysis. The result has been most satisfactory and in every case improvement has been shown and at times the whole existence of the patient has been profoundly modified as in the case quoted below.

Mode of action of stramonium.—The nerve centres controlling tone are situated at the base of the brain in the corpus striatum and in the substantia nigra of the crura cerebri. The centres are in turn controlled by impulses from higher centres. Injury to them, as in Parkinsonism, results in excessive tone (rigidity) in the voluntary skeletal muscles. Stramonium contains hyoscyamine, hyoscine and atropine. Drugs of this series abolish the tone of involuntary muscles by paralysing the parasympathetic, *vide* their effect in asthma, but have no action on motor nerves. The injection of cocaine in paralysis agitans abolishes the rigidity by paralysing the sensory nerve endings. Atropine applied locally also paralyses sensory nerve endings, but when given by the mouth it is not considered to have local action. Nevertheless, stramonium by the mouth abolishes post-encephalitic rigidity.

A case of post-encephalitic Parkinsonism

K., a single male, aged 25 years, vegetarian, was admitted on 17th October, 1934, into my ward in King George's Hospital, complaining of (1) weakness and rigidity in both legs with inability to walk, (2) a similar condition in both arms and in the head and the neck, (3) drowsiness by day and insomnia by night, all for the past three months, and (4) excessive salivation for two weeks.

History of present illness.—Nine months back the patient set out from Travancore on a pilgrimage to Rishikesh, which he reached in 14 days and where he lived with Sadhus for five months. During this period he was quite healthy. About three months ago, he got fever which lasted for a few hours and was accompanied by slight shivering. The following day he had a second attack of fever for a similar period. This intermittent type of fever continued for 10 days. He lost his appetite and sleep and became constipated. There was no history of headache, hiccough, vomiting, diplopia, or ptosis, nor of incontinence, but occasional

incontinence was observed after his admission to hospital. A few days after the fever, the patient appears certain (though his memory is definitely impaired) that he noticed slight weakness in his right arm; then his left arm became weak; then his head and neck; then both legs at the same time; and within a month he could only hobble, all bent and stiff, with the help of a stick. There is no history of any important illness nor of exposure to venereal disease.

Clinical condition on admission.—The patient lies quiet and drowsy in bed, mostly on his left side with the knee drawn up (figure 1). He

Fig. 1

pays no attention to what is passing round him. The left position is maintained since owing to the weakness and drowsiness considerable difficulty is experienced in turning over. The patient can be readily roused from his stupor if shaken or spoken to sharply, but rapidly becomes apathetic again. He is unable to dress himself and does not ask for food, but will stretch out his hand to take food if he is told to and the food is placed near him. He cannot write, though formerly he did so. He does not leave his bed for defecation, nor to pass urine, but usually calls the ward boy in good time. Occasionally incontinence is present. His body is thin. His face is immobile and mask-like. His head is moved little and his neck is rigid. When his attention is attracted by a noise at one side he turns his eyes in that direction first and not his head. His head, neck and vertebral column move as though they were connected in one piece by a rod of iron. All his movements are laborious, stiff and slow. Mentally he is decidedly dull. He takes long to understand and to reply to questions (slow cerebration). He speaks very slowly. His memory is markedly impaired. Though by day he is always drowsy yet he complains of insomnia and his sleep was much disturbed. Occasionally his eyes deviate outwards and remain fixed for a few seconds (third and sixth nerves) and then float inward again (oculogyric crises). On

closing his eyes, both eyelids quiver rapidly in recurring rhythmic movements. His lips are frequently pursed together. On making an effort to talk his lips also vibrate rapidly (seventh nerve). When he protrudes his tongue, marked fine tremors are noticed (twelfth nerve). He frequently opens his mouth slowly and closes it again (fifth nerve). Dribbling of saliva from the corners of the mouth is present (bulbar involvement). There is no squint, no ptosis and no diplopia. The left

Fig. 2.

seventh nerve is definitely weak, from a nuclear lesion as the forehead wrinkles normally. He does not voluntarily sit up in bed, much less stand or walk. When forced to walk he can only do so very slowly, stiffly and with the greatest difficulty. His shoulders are round and bent forwards and so is his body at the waist. Both upper and lower extremities are weak and spastic, but the right arm is more spastic than the left. The right upper extremity is held semi-pronated, flexed at the elbow, adducted, and with slight ulnar deviation at the wrist. The fingers are partially flexed at the

metacarpo-phalangeal and at the inter-phalangeal joints. The thumb is adducted and flexed over the index finger as in paralysis agitans except that thumb and finger tremors are absent. The patient cannot voluntarily extend his fingers. The grip is impaired. The biceps, triceps and supinator reflexes are brisk on both sides. The abdominal reflexes are present. In the lower extremities, the stiffness is marked, especially on the right. Reflexes on both sides are brisk, more so on the right (tendency to right-sided involvement). Babinski's sign and ankle clonus are absent. The feet on both sides are hyperextended and are somewhat inverted. There is no loss of sensation. The fundus is normal. The spleen is not enlarged. The other systems are normal. The cerebro-spinal fluid

the fever was controlled with quinine, atabrin and plasmochin.

Diagnosis.—The rousable lethargy, the oculogyric crises, the Parkinsonian-like rigidity, the spontaneous involuntary movements in the opening and closing of the lower jaw, with the eyelid, lip and tongue tremors and occasional incontinence left little doubt that the patient was in the chronic stage of encephalitis lethargica.

On the 20th December, the cerebro-spinal fluid showed the following results:—Wassermann reaction—completely negative, albumin—0.15 per cent, no organisms, and two cells per c.mm. The differential diagnosis from meningitis was supported by there being no characteristic changes in the cerebro-spinal

Fig. 3.

(19th October, 1934) was under no increased pressure; 15 c.cm. were withdrawn. Eight cells (mostly lymphocytes) were counted per c.mm., the albumin was 2 per cent, chlorides 67 per cent, and sugar 1 per cent. The Wassermann reaction of the blood and of the cerebro-spinal fluid was completely negative.

On the 17th October, 1934, the day of his admission, the patient's temperature was 105°F. falling to normal and again rising to 102°F. on the 18th October. After the 18th the temperature remained normal for three days when it became definitely tertian for three paroxysms. Though on the 19th October the blood report was negative to malarial parasites, yet the clinical diagnosis of malaria being established,

fluid, from poliomyelitis by the absence of any sign of lower motor neuron lesion, from crossed paralysis due to a tumour or vascular lesion in the pons by the onset of the disease with fever and without signs of any rise in intracranial pressure, as shown by the normal fundus and normal pressure; and finally from syphilitic cerebral lesion by the absence of a positive Wassermann reaction in the blood and in the cerebro-spinal fluid.

Pathology.—In encephalitis lethargica the grey matter of the cortex and of the basal nuclei is rosy pink from inflammation, whilst the white matter is not involved. In the rigidity and the tremors of post-encephalitic lethargica, as in paralysis agitans, the motor

cells in the grey matter of the substantia nigra of the crura cerebri, in the grey matter of the corpus striatum (caudate nucleus and globus pallidus of the lentiform nucleus), and in the grey matter of the subthalamic region (red nucleus and nucleus of Luys) are especially involved. The typical symptoms produced are rigidity, tremors, slow and weak voluntary muscular contractions, and spontaneous involuntary movements. The mental lethargy is probably due to involvement of the cerebral

of the fifth, seventh and twelfth nuclei in the floor of the fourth ventricle.

Treatment

The modern treatment of post-encephalitic Parkinsonism follows three distinct lines:— (1) stramonium, (2) physical drill, and (3) psychotherapy.

Method of giving stramonium.—A start is made with 30 minims of the tincture of stramonium in half an ounce of water thrice daily after meals. Five minims of the tincture is added thrice daily every other day until slight dryness of the mouth or paralysis of accommodation is observed. Then pilocarpine nitrate gr. 1/10th is added to each dose. The stramonium may be increased to one drachm thrice daily with up to 2/5th grain of pilocarpine nitrate. The dose of the two drugs on which the patient feels best is continued for life. In the alternative, pilocarpine may be omitted, and that dose of stramonium only determined which is found best suited to the patient.

Stramonium treatment of this patient.—Tincture of stramonium, 30 minims thrice daily, was prescribed from 16th November, 1934. Within three days the lethargy was diminishing and the patient began to take far more interest in the events around him. He commenced to sit up in bed. On the 21st November, of his own accord, he left his bed to bask in the sun. He started to walk around, which he had not done for the last four months. On this day, a five minutes' walk was prescribed four times daily as part of his treatment. On the 28th November he was able to feed himself and asked for the food delicacies he liked. On the 2nd December he dressed himself and on the 3rd December he went to the bathroom unaided. He now started to desire to earn his living.

Physical drill.—The patient was instructed in physical exercise, such as rising on tip-toe, whilst extending his arm and raising it above his head (figure 2). Later, he was prescribed more complicated exercises and was re-taught to run. The number of times each exercise was to be performed was definitely laid down.

Psychotherapy.—The patient was improving mentally as well as physically. He felt the change in himself, and was very happy. Every morning he would tell the doctor, the students and the nurses that he was feeling much stronger. He was encouraged and praised at every success, he was given tumblers of water to carry about the ward, and some useful light ward duties. He massaged himself with oil with the twofold purpose, that mechanical movement and massage were good for him, and that active mental effort was initiated. The patient was thus encouraged to work for himself and for others as much as possible. Cerebral re-education, physical and mental, was helped in every possible way.

Diagram showing motor nuclei

... Nuclei affected.

Fig. 4.

In the case quoted, the fifth (temporal and masseter muscles), the seventh (eyelids, lips and tremors) and the twelfth nuclei (the tongue tremors) were affected.

cortex. The left facial paralysis, with increased rigidity of the right side of the body, was a crossed hemiplegic manifestation arising from a lesion especially developed in the upper part of the left pons—where the face nucleus for the same side is (see diagram). The eyelid, lip, tongue and jaw tremors are due to involvement

A Mirror of Hospital Practice

CYSTS OF THE SPLEEN

REPORT OF A CASE

By M. M. CRUICKSHANK

LIEUTENANT-COLONEL, I.M.S.

General Hospital, Madras

Cysts of the spleen are sufficiently rare for the report of a single case to be warranted.

A male child of seven years was admitted to hospital on 16th April, 1935, with marked distension of the abdomen. The mother gave an indefinite history of periodic attacks of fever for the past three months.

Examination of the heart.—Left border in the nipple line. Mitral systolic bruit present.

Examination of the abdomen showed some dilatation of the superficial veins, these extending on to the thoracic wall. The abdomen was distended, more markedly so over the left upper quadrant. Palpation revealed a very large spleen bulging from below the costal margin and extending downward to the level of the left iliac crest and inward to just beyond the middle line. A slight rub due to some perisplenitis was felt and percussion showed the presence of some free fluid in the abdomen.

There was some doubt as to whether the mass might not be a kidney tumour, but intravenous pyelography, with uroslectan B, excluded any kidney lesion, calyces and ureters on both sides presenting normal shadows.

The blood picture was normal, as also was the Wassermann reaction.

Splenic puncture produced a dark straw-coloured fluid, which contained albumin, no sugar and no scolices.

Under open ether, the abdomen was opened through a T-shaped incision. The spleen was largely cystic, the bulk of the spleen tissue lying against the ribs.

Any attempt to remove the spleen was negatived on account of dense adhesions to the under surface of the diaphragm and also because gut and omentum were firmly adherent to the cystic tumour.

The tumour was punctured with a trocar and cannula, through a thin superficial layer of splenic tissue, and about twenty ounces of a dark straw-coloured fluid allowed to run off, the cavity then being mopped dry with gauze. A de Pezzer's catheter to drain the cavity was tied in with a purse-string suture, the cyst wall stitched to the abdominal parietes and the abdomen closed. There was no true cyst wall present, the wall being formed by compressed splenic tissue.

The result of biochemical and bacteriological examination of the fluid was:—

Microscopically no organisms seen.

No scolices seen.

Culture—sterile.

Albumin—0.6 per cent.

Globulin—0.3 per cent.

Cholesterol present.

Discussion

Boyd classifies cysts of the spleen as

1. Hydatid.
2. Dermoid.
3. Simple.
 - (a) Hæmorrhagic.
 - (b) Seros.

The hæmorrhagic cyst, the result of trauma to the spleen pulp, in which vessels are easily ruptured, due to the absence of an elastic coat

is, according to Boyd, the commonest form of splenic tumour.

Moynihan gives a much more exhaustive classification of the varieties of spleen cysts, which I give in detail:

A. True cysts with a definite lining layer, epithelial, endothelial or parasitic.

1. Angiectatic { Telangiectasis { Dilatation
Lymphangiectasis { of normal
vascular spaces.
2. Neoplastic { Endothelial { Hæmangioma.
Dermoid { Lymphangioma.
3. Parasitic Hydatid.

B. False cysts bounded by a zone of condensed tissue only.

1. Traumatic { Seros—Multiple and
superficial.
Hæmorrhagic—Large and
solitary.
2. Inflammatory { Acute—Colliquative
necrosis.
Chronic—Tuberculous.
3. Degenerative { Secondary liquefaction of
infarcts.

Large hæmorrhagic cysts are the result of injuries, where the vessels in the spleen are torn and hæmorrhage occurs, and, if the patient survives, a cyst forms the contents of which are blood-stained or, more rarely, pale yellow in colour. A hæmatoma is formed and, as occurs in a cerebral hæmorrhage, instead of becoming absorbed, the clot undergoes softening and liquefaction forming a cyst, the walls of which consist of tough fibrous tissue. In time the blood pigment is absorbed and is replaced by masses of cholesterol crystals, which are present in the wall of the cyst, the colour of the contents therefore changes from a blood-stained to a clear yellow fluid. Such a change naturally takes time, probably months, to occur.

Degenerative cysts are the end result of splenic infarcts, the infarcts undergoing softening, the resulting cysts containing turbid serum or altered blood with cholesterol crystals.

According to Boyd, however, a splenic infarct becomes converted eventually into a mass of fibrous tissue.

In inflammatory cysts the colliquative process results in the formation of a cavity containing blood-stained purulent fluid, the walls being formed by and lined with shaggy and much altered splenic tissue.

According to Moynihan's classification, the cyst in question was a false one, yet it is difficult to decide definitely whether it can be classified as traumatic or degenerative. The large simple cyst containing straw-coloured fluid, with cholesterol crystals, is in favour of a hæmorrhagic cyst, but no history of trauma could be obtained. The condition of the heart might

favour the diagnosis of a secondary degenerative cyst, the result of an infarct.

The character of the fluid and the uniform smoothness of the wall rules out an inflammatory cyst.

TREATMENT OF MULTIPLE WARTS

By R. C. DALAL, L.C.P. & S. (Bom.), S.M.S.
Medical Officer in charge, Dispensary Tankaria
(District Branch)

THE remedies employed in the treatment of common warts have ranged from magic charms to surgical excision, and acids, electricity, carbon dioxide snow and radium have all produced good results in many cases. However, when a large number of warts are present, local destructive measures are tedious and painful and, in children, such treatment is difficult to carry out.

Case.—A girl, aged about 10, was brought to me by her father for the treatment of dark brown elevations on the back of the hand and neck.

On examination I found that they were soft, fleshy and lobulated. From the history it was evident that they were congenital, and that they have increased in size in the last three years.

Treatment.—On the first day I gave the following powder which I instructed her to rub well over the parts and to report on the fourth day.

R/Acid salicylas	..	1 drachm.
Acid boric	..	3 drachms.
Calomel	..	6 drachms.

The man returned with the girl on the fourth day with no change in the condition of the warts.

Then I tried the following prescription, the medicines to be applied externally, and gave her some to apply at home.

R Sulphur sublimatum	..	10 drachms.
Glycerine	..	3 drachms.
Acid acetic	..	5 drachms.

The girl was brought again after a week with no appreciable change in the condition. During this week I happened to read that bismuth injections were specific for the complete destruction of warts, when a large number are present. Accordingly I began with Bismuth salicylate gr. 12 intramuscularly, in the upper outer gluteal quadrant. After a week a second injection was given. During the second week, regression began and I did not give any further treatment until the condition became stationary. Subsequently a third injection was given at an interval of two weeks and after four injections the warts had disappeared.

A CASE OF PELLAGRA

By M. S. H. MODY, M.B., B.S. (Bom.), L.C.P.
M.R.C.S. (Eng.), D.T.M. & H. (Lond.)
Honorary Physician, Sassoon Hospital, Poona

A MALE, aged 24 years, farmer, resident of Saswad (16 miles from Poona), sought admission to the hospital for diarrhoea and inability to walk.

Eight months previously he had an attack of diarrhoea (8 to 10 stools a day), and also developed dark brown pigmented areas on his face, neck, and back of his hands and feet. He felt very weak and was unable to walk without help. He seemed to improve after a month or so and was able to attend to his work on the farm, but in a short time a second attack of the

same complaints occurred, which confined him to bed, as he was unable to walk at all. He also developed glossitis, which prevented him from eating his usual diet.

On admission.—There was a well-marked butterfly-shaped pigmented area, dark brown or almost black, on his face, the dorsum of both hands and the back of his neck were also deeply pigmented. The skin of his hands besides showing the characteristic pigmentation, was very dry and rough and at places peeled a little. The gastro-intestinal symptoms—diarrhoea and stomatitis—troubled him much, the entire buccal mucous membrane was red and inflamed, and the tongue appeared glazed and shining (atrophic glossitis).

Rigidity and spasticity of both lower limbs, with exaggeration of all jerks characterized the nervous manifestations. There was no anaesthesia and he had complete control of his sphincters; ankle clonus and the extensor type of plantar reflex were absent. The spastic paresis made walking almost impossible. He showed the mental state of pellagra in a marked degree, as he was very taciturn and morose, and when spoken to and interrogated he said that he would never get well, whilst at other times he suffered from hallucinations, thinking he was to be operated upon.

In the diagnosis, syphilis, leprosy, and ankylostomiasis were excluded by the usual laboratory investigations.

Treatment.—Immediate improvement began after putting him on a diet liberal in proteins and vitamins, viz. meat, fresh liver, milk, dal, and fresh vegetables in large quantity, marmite and fruits. In addition he also received 'Abidol'. He is now able to walk unaided; the dry and desquamating pigmented areas on the skin have completely disappeared. The former troublesome diarrhoea is now replaced by constipation, which is equally troublesome and needs treatment.

The only symptom that shows no improvement is his pessimistic mental attitude; he still maintains that he is not better and he will never be cured.

Nothing abnormal in the way of diet or mode of life can be found to have any bearing as regards the causation of his disease. His diet is in keeping with his poverty and condition of life, and more or less is the same as that of the vast majority of such ryots, the staple articles being *jowari* chapatis with a little fresh vegetables and dal. Milk, ghee and fruits are a very rare delicacy. He admits taking alcohol, but has left off drinking for the past two years.

REMOVAL OF A LARGE OVARIAN CYST

By RAO SAHIB B. C. VACHHARAJANI, L.M. & S., D.M.S.
Medical Officer in charge, Civil Hospital, Godhra

A WOMAN, aged about 30 years, was admitted into the Mrs. Smart Victory Hospital on 24th June, 1935, for the enlargement of the abdomen, of about three years' duration: the swelling occupied the whole abdomen from the symphysis pubis to the xiphisternum, the measurement at the level of the umbilicus being 70 inches: she said that it first began in the left iliac region and that she was tapped two and a half years ago and some fluid was taken out; the abdomen started getting bigger again and for the last five months it was increasing rather rapidly; lately she experienced difficulty in walking unaided; the skin of the abdomen was shining, the veins were prominent, a thrill was present and she experienced difficulty in taking any food.

The cardiac, pulmonary, and nervous systems were normal. Urinary system was normal.

Vaginal examination.—Cervix normal, movable and low in vagina; she was menstruating regularly every six weeks; she had one child twelve years ago, who is alive.

A provisional diagnosis of an ovarian cyst was made and the abdomen was opened in the usual way. The tumour was found to be so large that it was impossible

for one assistant to lift it out of the abdomen to ligature the pedicle, which was short and broad. It was therefore tapped and most of the fluid, which was black in colour, was removed in this way; adhesions were broken and two strong ligatures were put round the pedicle and the tumour was removed. The total weight of fluid was 46 pounds and that of the sac 2 pounds which is by far the largest I have met with in my surgical practice of over 22 years. I do not like to tap such tumours before removal but in this case it was impossible to adopt any other course. The abdomen was closed layer by layer in the usual way and the woman made an uneventful recovery.

A CASE OF ASCITES TREATED BY AUTOSEROTHERAPY

By BEHARI LALL KAMRA, M.B., B.S.
CAPTAIN, A.I.R.O.

Medical Officer in charge, Rattewala Dispensary,
Ferozpur District

A FEMALE, 19 years of age, was admitted on the 7th December, 1934, to Rattewala Dispensary, with swelling of the feet and legs and enlargement of the abdomen of 1 to 1½ months' duration. About 6½ months ago the illness started with an attack of dysentery, which lasted for about 5 months. About 3 months after the beginning of the illness she aborted and got a left mammary abscess, which ruptured spontaneously and had healed.

The abdomen was uniformly enlarged. The girth measured 34 inches at the umbilicus, which was nearer to the pubes than to the ensiform cartilage.

The abdomen was dull in the flanks and tympanitic in front. The spleen and liver could not be palpated. Fluid thrill and shifting dullness could be easily elicited. Her heart was normal. The pulse was 120 per minute and was small. Moist râles could be heard at both bases of the lungs. There was no jaundice. Edema of both feet and legs was present and came on before the ascites.

She was put on the following mixture:—R. Tincture digitalis— η xx, spiriti ammonii aromatici— η xx, tincture nucis vomici— η v, spiriti ætheris— η xx, aqua ad 1 oz. three times a day. Paracentesis abdominis was performed the same day, and about 20 pounds of clear fluid withdrawn. Its specific gravity was not taken nor could its chemical and microscopical examination be done. After tapping, the girth at the umbilicus measured 30 inches.

One cubic centimetre of the ascitic fluid was given subcutaneously immediately after tapping and some was stored in a sterile phial out of which 1.5 c.cm. and 3.5 c.cm. were injected under the skin on the 11th and 15th December, 1934, respectively. On the 22nd December she was again tapped, and about 12 pounds of fluid withdrawn—this time it was greenish in colour—5 c.cm. was injected, and on 26th December an injection of 10 c.cm. of the stored fluid was repeated.

Whatever amount of the free fluid was left behind after the last tapping now began to be absorbed instead of re-accumulating and on 5th January, 1935, not a trace of it could be detected. The spinal column could easily be felt through the anterior abdominal wall. There was absolutely no swelling of the feet.

Since admission she had been passing four stools a day, on the average. They were always semi-fluid and occasionally contained blood. On microscopical examination they were found to contain cysts of *Entamoeba histolytica*. On 16th January, 1935, she was put on emetine hydrochloride, hypodermic injection of gr. i a day for six days. After an interval of three days three more injections were given and a course of twelve injections was completed after another interval of three days.

The blood and mucus disappeared from the stools and their number was reduced to 1 to 2 a day though

they were still semi-fluid in consistency. A few days after the course of injections was completed the woman showed signs of muscular weakness, starting in the lower limbs, on account of which she was again bed-ridden and was unable to stand up although she could sit. Salol was prescribed and she was discharged on 6th February with emetine paresis but cured of ascites.

She attended the dispensary on the 22nd April, 1935. She came on horse-back from a village five miles away and could walk in all right but was feeling weak in the legs and arms. There was a moderate degree of anæmia. There was absolutely no trace of free fluid in the peritoneal cavity. The urine was normal; no cysts could be detected in the stools which contained no blood and looked quite normal. The liver was palpable.

Evidently this was a case of ascites due to non-suppurative peritonitis and belonging to a class which Megaw (1921) studied and was named 'chronic superior peritonitis' by Sprawson—(Megaw *loc. cit.*), while the presence of amœbic cysts might have been due to an infection superimposed upon an attack of bacillary dysentery. Chronic superior peritonitis causes ascites as the result of fibrosis of the peritoneum following its inflammation. These cases follow diarrhoea or dysentery, probably caused by the bacillus of Flexner or some closely related organism.

Autoserotherapy in ascites is not a new thing. It has already been tried though the reports have not been favourable and conclusive. It may be useful only in the class of cases termed chronic superior peritonitis and the unfavourable results might have been due to treating cases of ascites other than this type. The successful application of autoserotherapy in the above described case has prompted me to report it so that others may try this treatment.

I am greatly indebted to Lieut.-Col. Batra, I.M.S., Civil Surgeon, Ferozepur, for his useful advice and kind permission to publish this note.

AN UNUSUAL CASE OF CANCRUM ORIS*

By MAGANLAL D. LATHIGARA, M.B., B.S.

Medical Officer, Bilkha State, Bilkha (Kathiawar)

A MALE adult, aged about 24, came to the state dispensary, complaining of toothache on 17th June, 1935.

On examining him I found the two upper lateral incisors painful and the gums over them red and inflamed. Potassium permanganate gargle, tooth powder and gum paint was prescribed. He attended the dispensary for about five days and then ceased coming. The patient did not take any further treatment. He returned on 11th July with a foul-smelling gangrenous slough over the upper lip on the left side just below the left nostril which was partially eaten away. On examining the mouth the gums were found to be gangrenous and both the teeth were loose. Inside the mouth, the mucous lining over the left cheek was black and sloughing, with a very foul odour. His pulse was rapid (110), and he had a temperature over 100°F.

* Rearranged by Editor.

He did not complain of much pain and could take liquid food.

Suspecting the case to be one of acutely spreading gangrene I removed the two teeth and a considerable portion of the slough. On cleansing the part a hole appeared which communicated directly with the oral cavity, just below the left nostril. I irrigated the cavity thus formed with warm Milton lotion and packed it with sterile iodoform gauze. Potassium permanganate gargles were ordered and complete isolation from flies was strictly advised. He attended the dispensary as an outpatient for about a week, during which time the above treatment was carried out. He flatly refused to take any injections. His condition was going from bad to worse and his facial gangrene was spreading.

On the 16th July, when I examined him the gangrene had spread over the cheek and the left side of the nose was destroyed. I had to dissect out the slough daily and by this time the whole of the left nasal cavity was exposed and the gangrene had spread up to the eye. He was unable to walk and refused any food. I advised him to go to a hospital and to get admitted there as an inpatient. He agreed to go but absconded after four or five days and took no treatment for about a week, during which period he was confined to bed at his home and his condition became much worse.

I went and saw him on the 29th July and found the nose completely destroyed, and the nasal and cheek bones exposed. The left eye was gone and the bony margins of the orbit were visible. The lips were also gone and the jaws exposed, and the whole area was crawling with maggots. In spite of the seriousness of his condition he complained of no pain but only irritation caused by the maggots. It was not possible to do anything for the man so I just sprayed the area with weak lysol and removed a number of maggots. He died on the 31st July.

The unusual features of this case are :—

- (1) Cancerum oris is usually a disease of childhood and is comparatively rare in adult life.
- (2) In this case it began as a mild gingivitis.
- (3) The patient was not weak, nor was his vitality lowered so as to account for this acute gangrene of his face.

SPONTANEOUS BURSTING OF A STONE IN URETHRA

By B. R. JAIN, M.B., B.S., F.M.S.

Medical Officer, Konch, Jalaun, United Provinces

A MAN, aged 36 years, was admitted on 20th April, 1935, with retention of urine and extravasation for the last 36 hours.

He gave no history of venereal disease, but had had pain on micturition for the last year, recently becoming worse. About a week ago when the pain became very severe he went to Nadigaon hospital. Here he was given 'something to apply' and he went home. That day while straining in the act of micturition, he felt something give way inside and after that his pain increased. Thereafter he only passed urine with great pain and in drops, and for the last thirty-six hours he has not passed any urine at all. He denies all history of instrumentation.

Present condition.

General.—Patient suffering from severe toxæmia, face drawn, quick and feeble pulse, restlessness, rapid breathing.

Local.—Scrotal tissue oedematous and gangrenous; superficial cutis peeled off exposing red skin beneath;

skin over pubis and right loin red and indurated. Blisters have formed over loin. A similar condition of the skin is present in the perineum where also the cutis has disappeared exposing grey gangrenous tissue beneath.

Bladder region dull on percussion and tender on pressure. Distension up to just below the umbilicus. Bowels not moved for last three days.

Operation.—Under chloroform and other anaesthesia multiple incisions all over the scrotum were made. The incised tissue was gangrenous and urine trickled out freely from the incisions. The perineum was also similarly incised. A full-sized metal catheter was then passed from the external meatus. It went in easily as far as the prostatic portion and there a distinct stone click was heard and felt, and the instrument went no further. One of the cuts already made in the perineum was deepened and a finger put in through the perineal gangrenous tissue. The cut was further deepened by the finger and the stone reached. The stone was found already broken into pieces. Twelve pieces were removed by lithotomy forceps. (The total weight was 6½ drachms and the largest piece was about 1 by ½ inch by ½ inch. The stone was phosphatic and quite hard in consistency.) The catheter then went in easily and the retention was relieved. The wounds were dressed and the patient put to bed.

Shock and toxæmia were treated with glucose and stimulants, and urotropine was also given internally. The skin over the pubis and loin sloughed away during the next three or four days and a large slough came out through the perineal wound. The man was later on put on iron, quinine and digitalis and he steadily improved. On 29th April a full-sized (no. 12 English) catheter was passed, kept in place for ten minutes and removed. The patient passed one more small piece of stone through the perineal wound on the 8th May. On 10th May he had an attack of influenza and got better by the 14th. Thereafter a no. 12 catheter was passed every fourth or fifth day. On the 30th May, a plastic operation was done when the skin over his loin and pubis was undermined, and flaps brought together and sutured. Eight small skin grafts were also taken from the thigh and planted over the scrotal wound. Thereafter he made an uneventful recovery and was discharged cured on 23rd June, 1935.

The interest of the case was the spontaneous bursting of the stone which had obviously been forming in the membranous portion of the urethra anterior to the prostate. The man was very carefully interrogated about any instrumentation being done previous to his coming to this hospital. The medical officer of Nadigaon hospital was written to to find out if he had passed any instruments but he had not done so and the man denied all history of instrumentation previous to admission here. As I have never read nor heard of any stone bursting spontaneously by muscular action only, I am reporting this case.

I have to thank the Civil Surgeon, Jalaun, for permission to report this case.

A CASE OF ASTHMA TREATED WITH OLEO-SANOCRYSYN

By S. M. DAS, M.B.

Sylhet

Patient.—S. R., a Hindu female, aged 19 years.

Typical asthmatic attacks began in the latter part of August 1933, following a miscarriage. It was preceded by nasal catarrh and cough with expectoration

for one year. During this period of catarrh and cough the patient one day coughed up some blood. The period of this first attack lasted for one month, attacks used to occur at intervals of four to five days and lasted for two to three days.

Six months after the commencement in the latter part of March 1934, she had another attack of asthma. This attack was more severe; it lasted for three months. The duration of each attack was six to eight days with an interval of two to three days.

She had a respite for fifteen days followed by another attack like the last which began in the first part of July 1934 and continued up to the middle of October 1934, when she was put under the present treatment.

She denies any family history of asthma or lung troubles. About the past history there is nothing particular except that she had cholera five years back, a miscarriage three and a half years ago and has been suffering from gonorrhoeal endo-cervicitis.

The following conditions were noted when she was put under the present treatment in the latter part of October last:—

There was no attack when she was seen but she had an asthmatic tendency every morning and evening. There was cough with expectoration and rhonchi were present all over the lungs. In the sputum no acid-fast bacilli were found but diplococci and staphylococci were present. She was a little anæmic and a blood slide revealed a normal picture without any eosinophilia. Wassermann reaction was negative. No ova nor parasites could be detected in the stool.

Treatment.—She was allowed an easily digestible mixed diet; protein was not withheld as there was no eosinophilia. She was allowed to have a daily bath in cold water (she was having no bath for the last three months). Taking it to be a case of bronchial asthma she was first given malted cod-liver oil with hypophosphites and a course of six calcium chloride injections (10 per cent 10 c.cm.) twice a week. Cod-liver oil was continued for about three months.

After the course of calcium chloride injections was finished she was given four injections of oleo-sanocrysin in the following doses: 5 per cent 2 c.cm.—two doses and 5 per cent 3 c.cm.—two doses. The urine was examined for albumin before each injection. The injections were followed by some reaction in the shape of a slight rise of temperature and local and general bodily pain. An interval of ten to fifteen days had to be allowed between injections. The course was finished by the first part of January 1935.

All treatment was suspended for three months and then another course of oleo-sanocrysin was begun in the beginning of April last and finished by the first part of May last. The doses were as follows: 5 per cent 5 c.cm.—two doses, 10 per cent 3 c.cm.—two doses, 10 per cent 5 c.cm.—two doses, there were six injections in all. This time there was no general reaction so the injections could be given once a week.

After the initiation of this treatment she had no asthmatic attack and now the lungs are quite free. Although one might wait a little longer before passing any definite opinion about the merits of gold preparations in this case, such a long interval of freedom from attack is distinctly suggestive and encouraging.

I gave six injections of sanocrysin to another patient who had been suffering from mixed bronchial and allergic type of asthma. X-ray picture showed a very thickened bronchial tree, there was eosinophilia about 7 per cent and the patient had been suffering from chronic dysentery. The doses were as follows: 0.01 gm.—two doses, 0.025 gm.—two doses and 0.05 gm.—two doses. There was no evident improvement in the course of the asthmatic attacks. But when the sputum was examined after the completion of the course of injections it was found to be entirely free from organisms and the patient was almost completely relieved of her cough.

A CASE OF ACONITE POISONING TREATED BY HYPERTONIC SALINE BY THE INTRAVENOUS ROUTE

By M. TALUKDER, M.B. (Cal.)

House Physician, Carmichael Hospital for Tropical Diseases, Calcutta

Mrs. X, a private patient living in her own home, took about one ounce of liniment A. B. C. in mistake for *mistura carminativa*, the two bottles being together on her table. As soon as she had done so she realized her mistake and vomited the medicine as far as she was able to do. Medical aid was at once called in and her stomach was immediately washed out with potassium permanganate solution. I saw her after the stomach had been washed out the first time and noticed typical symptoms of aconite poisoning, *viz*, tingling and numbness of mouth and tongue, salivation, nausea and vomiting with epigastric pain. There was a marked sensation of burning in the gastro-intestine and she felt as if her tongue was becoming shorter and the throat blocked. She did not exhibit any of the symptoms of belladonna or chloroform poisoning because the aconite poisoning symptoms masked them. Her stomach was washed out a second time with potassium permanganate solution; but the woman gradually began to sink. Her pulse became rapid, irregular and weak, skin cold and clammy and there was profuse perspiration. She was very restless and was having frequent evacuations of the bowels. She was given injections of strychnine, digitalin, atropin, camphor in ether, adrenaline and caffeine at half-hour intervals and was kept warm by the constant application of hot-water bags and rubbing with powdered ginger all over her body and extremities. She continued to grow worse however, her pulse became more rapid, her eyes were sunken and she had difficulty in respiration. It was now about two hours from the time she had swallowed the liniment and her condition seemed hopeless. Her respiration failed four times and each time it was restored by artificial manipulation. Her radial pulse was imperceptible. On account of the amount of perspiration and evacuations with consequent dehydration I thought it might be of use to give hypertonic saline intravenously. Accordingly three pints of saline were given. Immediately her pulse greatly improved and she had no more attacks of dyspnoea. The pulse was still irregular and rapid and there were dropped beats now and then, but she appeared comfortable and slept for some time. Her improvement was steadily maintained and she was now kept only on adrenaline five minims under the tongue every two hours for twelve hours and then every four hours till forty-eight hours had passed. Her pulse and respiration gradually improved and became normal. At the end of seventy-two hours she was completely recovered. Her mind was quite clear from beginning to end.

This note has been published because, as far as the writer is aware, hypertonic saline has not been previously used in collapse following aconite poisoning, and as this form of poisoning is relatively common in India this record may possibly be of some value to practitioners.

A FOREIGN BODY IN THE HAND

By IQBAL AHMAD, L.S.M.F.

Civil Dispensary, Phularwan (Shahpur)

ON the 22nd of October, I. A., aged eight years, complained that he had severe pain in his hand and that he could not open it. He had a fall on the ground while he was playing.

On careful examination neither fracture, dislocation nor any other sign of injury could be detected to account for such severe pain. The patient told me

that he found a small thorn in his hand which he had removed. Tincture of iodine was applied and the hand bandaged. The inflammation went on increasing so much that, on the first of November, the hand could not be opened at all. The inflammation was more marked on the dorsal than on the palmar aspect. The patient was taken to Kapurthala, where he was shown to several doctors, who said that he had a dislocation of the hamato-metacarpal joint. By this time two small swellings had appeared on the dorsal and palmar aspects of the hand near the above-mentioned joint, and could be easily taken for the ends of the hamate and the fifth metacarpal bone.

On the 26th of November, the patient was taken to Amritsar for skiagraphic examination. At this time the inflammation had disappeared, but a small hard swelling, which was quite painless, had appeared on the back of the hand. Two surgeons were consulted, and the swelling was diagnosed as a fibroma in connection with the tendon sheaths. A skiagram was taken on the same day and the condition then was pronounced to be a chondroma in connection with the fifth metacarpal bone.

The patient was taken back to Phularwan, and it was decided to incise and remove the tumour. As he had bad health due to malaria, the operation was postponed till he improved.

On the 5th of December the swelling was incised under local anaesthesia. The swelling though tense and painless was pointing and a small white point which looked like pus could be seen on it.

On opening the swelling pus came out, and a small black dot could be seen in the wound. On catching the dot with forceps and pulling it out, it was found to be the point of an acacia thorn, which had entered through the palmar aspect of the hand and could not be detected before. It measured 1½ inches in length and was surrounded by a lot of granulation tissue which was scraped and the wound dressed. The patient made an uneventful recovery.

The points in this case are that :—

(1) Irritation caused by the foreign body in the hand led to periostitis. As the foreign body was transparent to x-ray, the radiologist was misled.

(2) As the swelling could be palpated on both aspects of the hand a dislocation was suspected.

TWO CASES OF CAISSON SICKNESS PRESENTING 'APHASIA' AS ONE OF THE CHIEF SYMPTOMS

By M. G. OKA, L.M. & S., B.M.S.

Civil Surgeon, Broach

THE following is a record of two cases of caisson sickness presenting aphasia as one of the chief symptoms. This is rare among the manifestations of the sickness. Usually the symptoms of caisson sickness appear immediately or within a short time after the patient comes out of the air-lock or diving suit, but in this instance they have appeared slowly and after a long interval.

Case 1.—On the 31st January, 1935, G. N., a workman on the Nerbudda bridge, being constructed by the Hindustan Construction Company, had to be seen by the medical officer. It was noticed that:—

1. The patient had lost the faculty of speech.
2. He could not produce any sound in his larynx.
3. His tongue movements unaffected.
4. His hearing capacity greatly impaired.
5. He was very apathetic.

On enquiry it was learnt that the workman had worked in the air-lock for six to eight hours daily for five or six days up to the 25th January. On the 26th he had outdoor duty and on the 27th he developed fever and his speech became incoherent. On the 28th the temperature became normal, but the defect in speech began to increase daily until on the 31st the patient could produce no sound. No paralysis of the limbs was noticed. The nerve reflexes were normal. No rigidity or flaccidity was noticed anywhere. His pulse was 74, volume and tension normal, regular in rhythm and force. There was no specific history and the glands not enlarged anywhere.

Diagnosis.—Caisson sickness. The patient was put in the medical lock* the same night after being given morphia gr. ½ and potassium iodide grs. 10.

COMPRESSION		DECOMPRESSION	
Time	Pressure per square inch	Time	Pressure per square inch
10-10 p.m.	0	10-40 p.m.	30 lb.
10-20 "	10 lb.	10-50 "	30 "
10-30 "	20 "	11-00 "	20 "
10-40 "	30 "	11-15 "	15 "
		11-55 "	5 "
		12-20 a.m.	0 "

With the increase of pressure in the medical lock the following improvements were noticed:—

1. Movements of larynx better; but yet he could not make any sound.
2. Hearing improved.
3. Apathy vanished.
4. Became more intelligent.

1st February.—Lacarnol injection and increased doses of potassium iodide.

2nd February.—A second course in the medical lock; at this time with 2-pound pressure, phonation power began to reappear and with 12 pounds the full power of speech was regained and has been maintained after decompression.

3rd and 4th February.—The patient was kept under observation and allowed to resume duty on 5th February.

Case 2.—R. A., aged 28, a coolie on bridge work, was admitted to the civil hospital on 12th January, 1935, with the following symptoms:—

- (1) Subnormal temperature;
- (2) rapid feeble pulse, weak heart;
- (3) deficient air entry at the base of right lung;
- (4) muttering at random;
- (5) blood-stained sputum.

The apathy of the patient was striking. Apyrexial pneumonia was the provisional diagnosis and treatment began on that basis.

Previous history.—Patient had worked in the air-lock for three months continually for about five or six hours every day. Three days previous to admission he had some remittent temperature with a little cough and laboured breathing. On the day previous to the admission he had passed a roundworm.

No specific history. Glands not enlarged. General build muscular.

The day after admission the temperature went up to 100.8°F.; pulse improved in volume and tension to 120. Respiration 35 and definite crepitations heard at right base. The mental condition was the same.

*The medical lock is a cylinder 6 feet in diameter and 12 feet in length. It is placed horizontally. It has an entrance of 2 × 2 feet which can be tightly closed. The air is admitted through an inlet pipe and is allowed to pass out through an outlet. Both the pipes have valves which can be regulated. The patient is placed in this cylinder and the door tightly closed. Air is then admitted to the required pressure, and then slowly let out. The whole process takes about 90 minutes.

received his qualification or qualifications, and shall request them not to admit him without previous reference to the Council to any examination for any new qualification, which is registrable in the register of registered practitioners. If a name is removed from the register, the registrar shall issue a notification in the *Calcutta Gazette* announcing the removal and forward a summary of the proceedings and findings to the medical journals for publication.

Disposal of appeals from the decision of the registrar preferred under section 23 of the Act

An appeal to the Council, preferred under section 23 of the Act, against a refusal of the registrar to register the name or any title or qualification of any person on the register of registered practitioners, shall be in writing and shall state the grounds on which registration is claimed, the names of the qualifications, and the dates on which and the authorities from whom they were received.

On receipt of such an appeal, it shall be referred to a committee of the Council for consideration and report.

The committee shall have power to call for the original diploma or licence, etc., from the appellant for inspection and also such other documentary or oral evidence as may be considered necessary by them.

At the conclusion of their enquiry, the committee shall make a report to the Council embodying such recommendations as they shall think fit to make, with the reasons for the recommendations.

The appeal, the committee's report on it, and all other documents in connection with the case shall be laid before the Council at their next session.

The date on which the appeal is to be taken up by the Council shall be notified to the appellant. The appellant shall also be allowed, if he so chooses, to represent his case before the Council, either by himself or by his legal representative.

Add the following new rules:—

Rules for the restoration of names to the medical register

RESTORATION AFTER NON-PENAL ERASURE UNDER SECTION 16 OF THE ACT

(1) The Council may restore to the medical register, if they see fit, the name of any person which may have been erased therefrom under section 16 of the Act.

(2) No application for the restoration of a name so removed shall be entertained unless it be accompanied by a declaration from the applicant setting forth the facts of the case, and stating that he is the person originally registered, and by one of the following documents:—

(a) Applicant's diploma;
(b) His certificate of registration in original;
(c) A certificate in the form reproduced below from two practitioners registered under the Act as to his identity;

(d) If the applicant is not resident in Bengal, a certificate signed by two persons, who shall be Magistrates or officers holding a commission in one of His Majesty's Services, Civil, Naval, or Military, or Justices of the Peace, or two resident practitioners registered under the Medical Acts.

(3) A fee of Rs. 5 shall be levied for the re-registration of practitioners whose names have been erased from the register under section 16 of the Act.

'I hereby certify that the aforesaid applicant is the above specified.....whose name formerly stood in the medical register with the following address and qualification*':—

Name †.....
Address.....
Registered qualification or commission.....
Date.....

* Here insert applicant's former address and registered qualification.

† Here insert name and address of person certifying.

RESTORATION AFTER PENAL REMOVAL UNDER SECTION 25 OF THE ACT

An application for the restoration to the medical register of a name removed under section 25 of the Act shall not be entertained before the ordinary meeting of the Council next succeeding that in which the removal was ordered.

If any person whose name has been removed from the medical register by direction of the Council, and who still possesses a qualification entitling him to be registered, makes an application to the Council for the restoration of his name to the register, the following shall be the method of procedure:—

(i) The application shall be in writing, addressed to the Council, and signed by the applicant, and must state the grounds on which the application is made.

(ii) The application shall be accompanied by (1) a declaration made by the applicant setting forth the facts of the case, and stating that he is the person originally registered, and (2) by one of the following documents:—

(a) Applicant's diploma;
(b) His certificate of registration in original;
(c) A certificate in the form reproduced below from two practitioners registered under the Act as to his identity;

(d) If the applicant is not resident in Bengal, a certificate signed by two persons, who shall be Magistrates or officers holding a commission in one of His Majesty's Services, Civil, Naval, or Military, or Justices of the Peace, or two resident practitioners registered under the Medical Acts.

Each of these certificates of identity shall be in the following terms:—

'I hereby certify that the aforesaid applicant is the above specified.....whose name formerly stood in the medical register with the following address and qualification*':—

Name †.....
Address.....
Registered qualification or commission.....
Date.....

(iii) The statements in the application must also be verified by certificates in writing, to be given by two medical practitioners registered under the Act or the Medical Acts resident in the neighbourhood where the applicant had been residing since his removal, who were and are well acquainted with him before and since the removal of his name, and they must testify to his present good character.

(iv) On receipt of the application, it shall be referred by the registrar to the Penal and Ethical Cases Committee, for consideration and report. Before an application is considered by the Committee, the Registrar shall notify the same to the licensing bodies whose qualifications were held by the applicant at the time his name was removed; and shall further, by letter addressed to the person or body (if any) on whose complaint the applicant's name was removed, give notice of the application and of the time when the Committee intend to consider the same.

(v) The Penal and Ethical Cases Committee shall consider the application and may, if they think fit, adjourn the consideration of it to a future date or require further evidence or explanations from the applicant.

(vi) The Penal and Ethical Cases Committee shall make a report upon the application to the Council in camera embodying in that report such recommendations as the committee shall think fit to make, with the reasons for the recommendations.

(vii) The application and the certificates referred to in paragraph (iii) shall be in forms VI and VII in

* Here insert applicant's former address and registered qualification.

† Here insert name and address of person certifying.

the appendix with such variations as circumstances may require. Printed forms shall be kept by the registrar who shall supply them to intending applicants.

THE ALL-INDIA MEDICAL CONFERENCE

THE Central Provinces and Berar Medical Association, Nagpur, will hold the XII session of the All-India Medical Conference at Nagpur, under the auspices of the Indian Medical Association, during Christmas week, provisional dates fixed being from 26th to 29th December, 1935. Besides the scientific section all subjects of vital interest to the medical profession in India, *e.g.*, rural medical relief, health insurance scheme, will be discussed. The scientific section and the exhibition will afford every medical man a good opportunity to see the advances made in this country in medical science. To make the Conference thoroughly representative of the medical profession in India, it is requested that all members of the profession should join the Conference and take part in the deliberations.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following candidates are declared to have passed the L.T.M. Examination, Session 1935:—

Passed with Distinction

(Arranged in order of merit)

Biswanath Kar, L.M.F., Government of Bihar and Orissa.
Radhanath Misra, L.M.F., Medical Officer, J. D. Ch. Hospital, Kantamal, Orissa.

Passed

(Arranged in alphabetical order)

Mehar Chand Abbi, L.S.M.F., Medical Officer, Nagrota Rural Dispensary, Kangra District.
Dharmal Beri, L.C.P.S., Rajindra Hospital, Patiala.
Kanukurthy Udaya Bhaskara Rao, L.M.F.
Prangovind Harivallabh Bhatt, L.C.P.S., R. M. O., State Hospital, Chhota-Udaipur.
Sunit Kumar Bhowal, L.M.F.
Sunil Chandra Biswas, L.M.F.
Profulla Kumar Bose, L.M.F.
Baidya Nath Chakrabarty, L.M.F.
Bimal Chandra Choudhury, L.M.F.
Chhajju Mal, L.S.M.F., Sub-Assistant Health Officer, Hoshiarpur.
Susil Kumar Chakrabarty, M.B., Medical Officer, Waverley Jute Mills, Shyamnagore, 24-Parganas.
Dalip Singh, L.M.F., Medical Officer in charge, Manjhooli Dispensary, District Gurgaon.
Abhaya Charan Das, L.M.F., Government of Assam.
Dayal Singh, L.C.P.S., Military Sub-Assistant Surgeon, Jammu Cantonment.

Jogesh Chandra De Sarcar, L.M.F.

Sambhu Nath Gangopadhyay, L.M.F.

Sudhir Chandra Ghose, L.M.F., Sub-Assistant Surgeon, Cawnpore Junction, East Indian Railway.

Gobind Ram Marwahi, M.P.L., Sub-Assistant Surgeon in charge, Jail Hospital, Mianwali.

Gopal Dass Naring, L.M.F., Medical Officer in charge, Nawai Dispensary, Jaipur State.

Pabitra Mohon Gulu, L.M.F.

Jyoti Prakash, L.C.P.S., L.M.F., Victoria Hospital, Ajmer-Merwara.

Kamul Nain, L.M.F., Victoria Hospital, Bharatpur.

Monoranjan Karmakar, L.M.F., Gandrapam Tea Estate, Jalpaiguri.

Manoharlall, L.M.F., Medical Officer in charge, State Dispensary, Tijara (Alwar State), Rajputana.

Md. Mohindkin, L.M.F., District Board, Purnea.

Nandlal Damodar Mehta, L.C.P.S.

Jitendra Nath Putatunda, L.M.F.

Khagendra Nath Roy, L.M.F., Corporation of Calcutta.

Sankara Kurup, L.M.F.

Durga Das Sanyal, L.M.F., House Physician, Campbell Hospital, Calcutta.

Girindra Nath Sinha, L.M.F., Medical Officer, Hazaribagh District Board.

Tribeni Prasad, L.M.F., Sub-Assistant Surgeon, Burma Railway, Mandalay.

Tupulur Viswanatham, L.M.F., General Hospital, Mandapam Camp.

The candidates whose appointments are not mentioned were private practitioners.

THE FIRST ALL-INDIA OBSTETRIC AND GYNÆCOLOGICAL CONGRESS, 1936

UNDER the joint auspices of the Bombay Obstetric and Gynæcological Society and the Obstetric and Gynæcological Society of Southern India, the first All-India Obstetric and Gynæcological Congress will be held at Madras on the 2nd, 3rd and 4th January, 1936. The sessions will be devoted to the consideration of subjects under the following three sections:—

1. Obstetric section,
2. Gynæcological section, and
3. Maternity and Child-Welfare section.

There will be organized in this connection a scientific exhibition, which will include exhibitions of scientific appliances, foodstuffs, drugs and scientific books.

Members of the medical profession are invited to attend the Congress.

Particulars with regard to the programme will be published later. Those who intend to contribute papers to any of the sections are requested kindly to communicate with the President of the Obstetric and Gynæcological Society of Southern India, Government Hospital for Women and Children, Egmore, Madras.

Current Topics

The Diagnosis and Treatment of Intestinal Amoebiasis

By JAMES C. PATERSON, M.D.

(Abstracted from the *Canadian Medical Association Journal*, Vol. XXXII, April 1935, p. 399)

A YEAR before the recent epidemic of acute amoebic dysentery in the United States and Canada, Craig estimated that between 5 and 10 per cent of the inhabitants of the United States were infected with *Entamoeba histolytica*. He obtained this figure from the results of fourteen independent surveys which had been made in different parts of that country. With such a degree of latent infection, it is not surprising

that an acute outbreak occurred in 1933; and, furthermore, if certain requirements for its transmission are again fulfilled, it is quite possible that other outbreaks may occur in the future. Intestinal amoebiasis, then, appears no longer to be a disease peculiar to hot countries, and for this reason the following observations, made during several years of practice in a part of Columbia where amoebiasis is prevalent, may be of interest.

Depending on the severity of the symptoms, cases of intestinal amoebiasis may be divided into three main types:—

1. *Acute amoebic dysentery*.—This is the type which runs a rapid and sometimes a fatal course, death resulting from exhaustion, from gangrene and perforation of the bowel, or from abscesses in other viscera.

This form is comparatively easy to diagnose, and, as a rule, responds rapidly to specific (emetine) therapy. Even the busiest practitioner, with neither the time nor the equipment to make more than the simplest laboratory tests, should be able to diagnose this type in its early stages and treat it successfully.

2. *Chronic amœbiasis*.—The diagnosis of this type is usually more difficult, and its treatment more protracted than that of the acute variety. The symptoms, however, are rarely urgent, and, as special laboratory procedures are often necessary for diagnosis, these cases lend themselves better to hospital than home management.

3. *E. histolytica* 'cyst-passers'.—This type is in reality a mild form of chronic amœbiasis, as some degree of destruction of the bowel wall is always present. Typical cyst-passers, however, are completely symptom-free. Their detection and treatment among food handlers is of paramount importance, both in preventing and controlling epidemics, and they are therefore of special interest to the epidemiologist and public health officer.

Dobell and O'Connor have described the pathological changes in the large bowel and the protozoal findings of each of the three types, in reverse order, as follows:

'The ordinary person infected with *Entamoeba histolytica* passes the cysts of the parasite in his stools. But he has the active forms of the amœba in the tissues of his gut wall, and precystic amœbæ in the contents of the intestine. If the amœbæ irritate his gut sufficiently he suffers from diarrhœa. . . . In his stool we then find, therefore, large numbers of precystic amœbæ—often mixed with cysts in all stages of development. If the injury to the intestine is sufficiently severe the patient suffers from amœbic dysentery. Blood and mucus escape from the ulcerated areas, carrying with them numerous amœbæ from the damaged tissues. The amœbæ now found in the stools are therefore the large active forms, often containing ingested red corpuscles. In typical cases of acute dysentery, precystic amœbæ and cysts are absent from the stool.'

It is apparent, then, that attempts to find active red-cell-containing amœbæ in patients with chronic amœbiasis, or cysts in cases with acute dysentery, are usually futile.

ACUTE AMœBIC DYSENTERY

Signs and symptoms.—As the name would indicate, the most prominent symptom is the frequent passage of bloody-mucoid stools, accompanied by some degree of tenesmus and pain. The diarrhœa may be very severe, but it rarely exceeds ten or fifteen movements in twenty-four hours. The stool is usually of moderate size, although if much tenesmus is present it may be so scanty that the patient is deceived into thinking himself constipated. It is highly odoriferous, and consists, typically, of a mixture of mucus and blood of a chocolate or 'anchovy sauce' colour.

Pain and tenderness of localized areas of the abdomen corresponding to the affected portions of the large bowel are also prominent symptoms. The cæcum, the junction of the descending colon with the sigmoid, and the flexures are the favourite sites of ulceration. The pain and tenderness may be such that appendicitis, cholecystitis, or peptic ulcer is almost perfectly simulated.

The temperature is seldom elevated except in advanced cases and those which have developed hepatitis. Emaciation, as a rule, is progressive, although some patients remain in a surprisingly good condition and insist on continuing their usual activities until an advanced stage of the disease is reached. The white cell count is usually normal, but may be raised to 10,000 to 12,000 in some instances. A higher degree of leucocytosis in a frank case of amœbic dysentery usually heralds the onset of amœbic hepatitis.

Diagnosis.—The diagnosis of acute amœbic dysentery may be made in three ways; viz, by the identification

of the amœba on microscopic examination, by the symptomatology and the macroscopic appearance of the stool, or by the therapeutic test with emetine. The last two methods of diagnosis, however, should only be used in special circumstances.

The one indispensable factor in the microscopic diagnosis of *E. histolytica* in a fresh stool smear from a case of acute amœbic dysentery is the presence of an amœba which exhibits active movement while at body temperature and contains ingested red corpuscles. Active amœbæ from stools which have been allowed to cool to room temperature, especially in temperate climates, are usually not *E. histolytica*. The stool must therefore be absolutely fresh; it should be passed at the physician's office, or if the patient is confined to his house the microscope should be taken there and used at the bedside. *Entamoeba histolytica* is recognized as a colourless body, three to five times the size of a red corpuscle, it manifests definite amœboid movement, and contains one or more red cells which roll about in the interior of the amœba as it flows across the slide.

The technique of examination is as follows:—The necessary apparatus consists of a microscope fitted with a 1/6-inch objective, an ordinary glass slide and coverslip, and a wooden applicator. The specimen must be collected in a dry container devoid of disinfectant or urine. A small piece of blood-streaked mucus is extracted with the applicator, smeared on the slide, the coverslip is applied and pressed firmly down, and the smear is then immediately examined.

The onset of acute diarrhœa in a person residing in a region where amœbiasis is epidemic may be considered presumptive evidence of *E. histolytica* infection. If the condition is not relieved by catharsis, and the typical macroscopic appearance of the stool is present, immediate institution of emetine therapy is justified, even if microscopic examination has already been found negative, or if for any reason it cannot be made at once. This course was followed by the English forces in the Mediterranean during the late war, i.e., emetine was begun while waiting for the laboratory report.

The therapeutic test with emetine is a necessary adjunct of the above and need not be considered further. It is of particular value in obscure cases of amœbic hepatitis, when, as often happens, the amœbæ cannot be demonstrated even on the most exhaustive examination. If the temperature and leucocytosis in one of these cases are lowered following emetine therapy the trouble can usually be considered of amœbic origin.

Treatment.—The patient should be confined to bed and kept on a liquid diet until the acute stage of the disease is passed. No red meat, alcohol, or starchy food should be taken for one month following the termination of treatment. Daily hypodermic injections of emetine hydrochloride must be commenced immediately the diagnosis is made. Bismuth subnitrate, which has a valuable astringent action in this disease, should be given in massive doses three to five times a day. Opium can be given in moderation if much pain or tenesmus is present. With such treatment the acute symptoms should be controlled in from three to five days, and sometimes earlier. More drastic measures, such as wide-open cæcostomy or appendicostomy, with bowel irrigation, should not, in my opinion, be attempted until emetine has been given a fair trial. As a matter of fact, I have never seen an acute case of amœbic dysentery which did not respond to this drug, so my experience with other methods is limited. It must be admitted, however, that emetine, although it relieves the acute symptoms and so saves life, unfortunately rarely cures. Some follow-up treatment with yatrien or with one of the arsenicals is therefore necessary in almost every instance. This should be begun on the cessation of acute symptoms or when the course of emetine is terminated, and be repeated whenever the amœbæ reappear in the stool.

CHRONIC AMOEBIASIS

Signs and symptoms.—The stage of the disease, in the variety of its symptoms, may simulate almost any gastro-intestinal ailment common to either temperate or tropical climates. Acute exacerbations, characterized by the frequent passage of painful, blood-streaked stools, may occur at any time, and are predisposed to by physical exhaustion, alcoholic or dietetic excess, and over-exposure to cold. These acute attacks should be classed and treated as cases of acute amoebic dysentery. As a rule, however, these patients do not particularly suffer from diarrhoea and when it is present it usually is of constipation.

and other symptoms of chronic dyspepsia are common. Pain and tenderness of localized areas of the abdomen, and palpable thickening of the caecum and sigmoid are other fairly constant features. Neurasthenia, loss of weight, and other indefinite symptoms are sometimes complained of by these patients.

On the whole the symptomatology is unsatisfactory, and if intestinal amoebiasis is not kept in mind the diagnosis may easily be mis-led. As in the acute variety, appendicitis, cholecystitis, and peptic ulcer enter into the differential diagnosis, and if there has been much tissue hyperplasia about a localized site of chronic ulceration, malignant tumour of the bowel or rectum may be confusing. Such tumours commonly occur at the junction of the descending colon with the sigmoid, where they may be felt as fusiform swellings the size of a hen's egg.

With the onset of hepatitis, a complication not infrequently encountered in untreated chronic or acute cases, the symptoms become more definite. Severe pain is felt over the entire hepatic area and is often referred to the right shoulder. The liver is enlarged and its lower margin extremely tender. Signs of involvement of the right lung base are sometimes present. Low-grade pyrexia, a definite leucocytosis, and symptoms of toxæmia are constant features. A description of liver abscess is outside the scope of this article; in brief, its onset is marked by chills, a leucocytosis of 15,000 to 25,000 (with not more than 80 per cent of polymorphonuclears), and by an exaggeration of all the signs and symptoms of amoebic hepatitis.

Diagnosis.—Except in the case of amoebic hepatitis which may be recognized by the therapeutic test with emetine, the only certain method of diagnosis is by the detection of *E. histolytica*, either in the stool or in the scrapings obtained at sigmoidoscopy. The search may entail many exhaustive examinations before it is rewarded, and for this reason hospital investigation is usually to be preferred for these cases. Once diagnosed, and while undergoing treatment, however, these patients may resume their normal activities, except when emetine is prescribed, in which case they should remain in bed until the course is terminated.

The laboratory diagnosis of chronic *E. histolytica* infections may be made by using three types of preparations—fresh stool smears, iodine smears, and hæmatoxylin-stained smears. Each of these is of value in identifying the cystic stage of the amoeba. The hæmatoxylin-stained smear, however, is the only satisfactory method of identifying pre-cysts and those motile amoebæ which do not contain ingested red corpuscles. As the cyst is the predominating form in the stools of most cases of chronic amoebiasis (unless saline catharsis has been employed), a few remarks on its more important characteristics may be of interest. In fresh stool smears, by which method *E. histolytica* cysts can be recognized in over 90 per cent of the cases, the diagnosis hinges on the presence of the typical chromatoid bodies. These, with the proper illumination, appear as highly refractile, cylindrical bars with blunt (but not splintered) ends. These chromatoid bodies are of such diagnostic importance that their presence will accurately differentiate the cystic forms of *E. histolytica* not only from the cysts of the non-pathogenic amoebæ but also from such confusing

objects as *Blastocystis hominis*, food particles, and oil and air bubbles. They are not present in every *E. histolytica* cyst in a given smear; if they are absent in all, which occasionally happens, an iodine-stained preparation should be made. This method will bring out the two pairs of small, eccentrically-placed nuclei, a number and arrangement which is another point of differentiation. If any doubt still remains about the identity of the cyst one should resort to a hæmatoxylin-stained smear. This rather elaborate method of staining will reveal not only the chromatoid bodies and the arrangement of the nuclei in the cyst but also the minute details of nuclear structure. Hæmatoxylin staining is of most value, however, in identifying pre-cystic forms and those motile amoebæ which do not contain ingested red cells. As a matter of fact, these last two forms cannot be satisfactorily identified, except perhaps by experts, in any other way than by their nuclear structure, and if they are the only ones present in a stool hæmatoxylin-stained smear should always be used.

Summarizing, then, fresh stool smears are satisfactory for the diagnosis of active amoebæ which contain ingested red cells (acute amoebic dysentery), and of cysts which possess typical chromatoid bodies; iodine smears are useful in the diagnosis of those rare cases in which the cysts do not contain chromatoid bodies; and, finally, hæmatoxylin-stained smears are essential for the identification of pre-cystic forms and those motile amoebæ which do not contain ingested red cells. With such a routine, an accurate differentiation of *E. histolytica* from the non-pathogenic *E. coli*, *E. nana*, *I. butschlii*, and *D. fragilis* can always be made.

In securing a stool for examination, a natural movement is best, but a mild laxative, such as alophen or cascara, may be given if no natural movement is present. The first semi-soft stool after such catharsis often contains cysts, and may therefore be used for diagnosis; later watery movements are unsatisfactory, as the cysts have all been washed away from the lower bowel and pre-cysts and motile amoebæ, which are diagnosed with more difficulty, are present in the watery stools. Watery stools are useless for diagnosis, as they invariably wash off the cysts. Saline catharsis, however, may be used in those cases of slight infections in which natural stools give persistently negative results. As a result of the violent purgation the stool of such cases will sometimes contain a few pre-cysts or motile amoebæ. The identity of these forms cannot, of course, be definitely established at this time, but, later, an exhaustive search can be made for cysts which now we can be sure will appear eventually in the stool. Finally, sigmoidoscopy, with the microscopic examination of the scrapings obtained from the base of ulcers found in the rectum or sigmoid, may be useful in the diagnosis of obscure cases.

Treatment.—The diet is important and should not include red meat, alcohol, or starchy food during treatment or for one month following its termination. If amoebic hepatitis is present, daily injections of emetine hydrochloride are always indicated. Cases which show definite signs of bowel irritation are also best treated with a preliminary course of emetine. This may take the form of emetine hydrochloride injections or emetine-bismuth-iodide may be given by mouth. Daily instillations of yatrien solution into the bowel are useful in those cases which are receiving emetine-bismuth-iodide. Follow-up treatment with yatrien or with one of the arsenicals is usually necessary after either form of emetine therapy. This may be commenced after a rest period of one or two weeks. For milder cases, yatrien (with or without long courses of bismuth subnitrate), and carbarsone or stovarsol, are usually sufficient. Patients receiving these drugs can safely continue their usual work. Periodic stool examinations should be made after each course of treatment, and a cure should not be claimed until at least seven consecutive daily examinations have been found to be negative.

E. histolytica CYST-PASSERS

Because these people do not complain of symptoms, it by no means follows that they are free from pathological lesions. *E. histolytica* lives at the expense of its host, and therefore some degree of ulceration of the intestinal mucous membrane is always present. The ulcers may have far-reaching and even fatal consequences. They may rupture a blood vessel and cause severe intestinal hæmorrhage; they may burrow through the bowel wall and produce perforation; the amœbæ may be carried to the liver, *via* the portal circulation, and set up an amœbic hepatitis or liver abscess. It is hard to imagine how such serious complications can suddenly develop in those who have never complained of symptoms, but it is a matter of record that they do.

The infection in these cyst-passers, then, is always dangerous and should be treated as soon as it is discovered. It is, however, of far greater danger to the rest of the community than to the cyst-passer himself. When present in a food handler, especially if he is careless in his personal hygiene, the infection may be passed on to many others. Cyst-passers, therefore, are of special interest to the public health officer, and if in epidemic of acute amœbic dysentery develops in a community they should be sought and forced either to undergo treatment or to change their work.

Diagnosis.—In the conduct of a protozoal survey, which is the most practical method of diagnosing these symptom-free cases, the preparation of hæmatoxylin-stained slides will be found to be of great service. Immediate fixation in Sclaudinn's fluid and subsequent passage through 95 per cent alcohol into 70 per cent alcohol are done at the point of delivery of the specimen, and the slides are then sent immersed in the last solution to the central laboratory, where staining is completed and the microscopic examination made.

Treatment.—With the exception of emetine, the various drugs in use for the treatment of chronic amœbiasis are indicated. Following one or more courses of yatren or one of the arsenicals, the stool should be carefully watched for a reappearance of the parasite.

MISCELLANEOUS DATA ON AMŒBICIDAL DRUGS

Emetine hydrochloride is given by subcutaneous injection in 1 grain daily doses for eight or ten consecutive days. During the course of its administration the patient should remain in bed. The toxic symptoms of over-dosage or idiosyncrasy are asthenia, emaciation, mental depression, neuritis, a soft and irregular pulse, and changes in the skin and nails. Actually, emetine does not appear to be nearly as toxic as current reports would have one believe, and in the course of many hundreds of injections I have only seen one patient who definitely appeared to suffer from its use. This individual developed a beri-beri-like polyneuritis of both lower extremities which only disappeared after prolonged stay in hospital. Minor symptoms of emetine toxicity, such as weakness and depression, are fairly common, but if the patient is kept at rest during the administration of the drug there does not seem to be any definite contra-indication to its use.

Emetine-bismuth-iodide is always administered orally. It should be dispensed in gelatin capsules, as keratin-coated tablets are not properly absorbed. The dose for adults is 3 grains daily for ten or twelve consecutive days, but the first two doses may be reduced to 1 and 2 grains respectively. The drug should always be given at night, four hours after the last meal. Vomiting and some degree of diarrhoea are indications that the contents of the capsules are being properly absorbed, but the former may be lessened by giving 10 to 15 minims of Tinct. Opii half an hour before the evening dose. With emetine hydrochloride, the patient should remain in bed while the drug is being given.

Bismuth subnitrate, after the method of James and Weeks, is administered in heaped teaspoonful doses (about 180 grains) well mixed in a glass of water, soda

water, or milk, three to five times a day, over a period of from one to three months. Toxic symptoms occasionally develop but these are said to be due to impure bismuth. Recently I have observed severe cyanosis and dyspnoea in two young infants who had received large doses (about 40 grains) of a supposedly pure product, and it appears that the formation and absorption of nitrous acid in the large bowel may sometimes be the underlying cause of these alarming symptoms. Regardless of their ætiology, however, they rapidly disappear following prompt purgation with magnesium sulphate.

Yatren is usually given by mouth, but may be used as a rectal instillation in combination with emetine-bismuth-iodide. Orally it may be given in doses of one to four pills (of 0.25 gram each), three times a day, for seven to fifteen consecutive days. Annoying diarrhoea is the only evidence of intolerance to yatren, and its dosage should be governed by the severity of this symptom. As a matter of fact, chronically-constipated individuals are almost the only ones who can tolerate more than six pills of yatren a day in comfort. When given by bowel, a cleansing enema of 2 per cent sodium bicarbonate solution should be injected first. An hour later, 200 c.c. of a warm, 2.5 per cent solution of yatren is introduced and retained as long as possible. The instillation may be repeated each morning for ten consecutive days.

Stovarsol (acetylarsone, paroxil, spirocid) is given by mouth in doses of two tablets (of 0.25 gram each) daily, or one tablet, morning and night, for one week. After a rest of seven days the same course is repeated. Toxic symptoms are those of arsenic generally, and usually take the form of an erythema. This drug should not be used in the presence of renal or hepatic disease. Carbarsone, which, experimentally, is less toxic but more amœbicidal than stovarsol, is given in doses of one capsule (of 0.25 gram), morning and night, for ten days. As with stovarsol, it should not be used when renal or hepatic disease is present.

Newer Methods of Treating Peptic Ulcer, Constipation, and Indigestion

By GEORGE CRILE, M.D.

(From the *New York State Journal of Medicine*, Vol. XXXV, 15th April, 1935, p. 422)

TWENTY-FOUR years ago in an Ether Day address at the Massachusetts General Hospital, I enunciated certain principles which have ever since found their application in the Cleveland Clinic in the development of certain methods of treatment and prevention of those diseases in particular which by virtue of their origin and nature we have termed kinetic diseases. Twenty years ago I performed the first of a series of operations in which adrenalectomy was either performed alone, or was combined with sympathectomy or with thyroidectomy or with both, for the purpose of lessening the 'kinetic drive' to which these diseases are due. Later we not only added peptic ulcer to the list of the kinetic diseases but found that constipation and indigestion might be due to the same kinetic causes, and we found also that bilateral denervation of the adrenal glands gave more permanent results than adrenalectomy because of the tendency of the remaining adrenal to compensation. Recently we have found that unilateral denervation with division of the greater splanchnic nerve is as effective as bilateral denervation in many cases.

We shall cite certain case histories which offer evidence in support of our assumption both that peptic ulcer, chronic indigestion, and constipation may justly be termed 'kinetic diseases' since they are due to pathologic physiology of the energy system, and that these conditions are ameliorated or cured by adrenal denervation, but first I shall discuss the rationale of this procedure in such cases.

That the psychic factor exercises a powerful control, not only of the gastric secretion but also of the entire digestive tract and digestive processes, is a matter of common experience, and that the adrenal glands are concerned in the production of these disturbances has been abundantly proved by the investigations of Cannon and others.

This power of the adrenal glands over the gastro-intestinal tract would appear at first sight to make all animals above the level of the reptiles equally liable to peptic ulcer, to indigestion, to constipation. Yet we know that this is not the case for wild animals do not have peptic ulcer nor indigestion and, even among humans, peptic ulcer and indigestion occur rarely in primitive man and are found most commonly among teachers, lawyers, physicians, clergymen, business executives, diplomats, and that large group in other walks in life that are worried and have many anxieties, have indigestion or are constipated. Among the different races those of a nervous, high-strung disposition are more liable to have digestive disturbances than are those of a more phlegmatic type. Thus peptic ulcer occurs more commonly in the Jewish and Latin races than in the Nordic races.

Where is the cause of this difference to be found? Anatomically it would seem that all animals and all humans possess alike an adrenal-sympathetic system, and that just as the heart performs the same function in each, the adrenal-sympathetic system should function alike in each with identical results. By such reasoning we are leaving out of account two other essential units of the energy system of man and animals, the brain and the thyroid gland. Let us study for a few moments the comparative anatomy of this energy system.

From the point of view of their control of energy we may consider the animal kingdom as divided into three groups, although of course no absolute grouping is possible as there must be an overlapping for some animals have characteristics which pertain to each of two of the proposed groups.

1. The first, which we call the protected group, includes animals whose safety depends upon chemical or mechanical devices such as carapaces, quills, poisons, odours, or upon concealment, such as the armadillo, skunk, porcupine, alligator. These animals require for safety but little expenditure of energy, and therefore the whole energy equipment is relatively small.

2. The second, which we call the pure energy group, includes animals whose survival depends upon the expenditure of energy in attack or escape, such as the lion, fox, antelope, squirrel.

3. The third, the strategy group, includes those animals which depend mainly for survival upon the direction of energy by a controlling brain.

In animals in the second or pure energy group the adrenals are larger and the adrenal-sympathetic system is more complex than in either of the other groups. In the protected group not only are all the units of the energy system relatively small but the adrenal-sympathetic system is exceedingly simple in its connections. In both the pure energy and the protected groups the adrenal glands are larger than the thyroid gland; in man the thyroid gland is larger than the adrenal glands and in both these groups the adrenal-sympathetic system is complex and more so in the pure energy group than in the strategy group. In a fox and squirrel, for example, the weights of the adrenal glands were respectively $3\frac{1}{2}$ and $7\frac{1}{2}$ times larger than the thyroid gland, while in man the thyroid gland weighs approximately twice as much as the adrenal glands.

The thyroid gland maintains the level of activity of the brain and its size therefore depends upon the rate and constancy of demands for energy production. The thyroid gland, therefore, has reached its highest development in man in whom the demands for energy are ceaseless. The size of the adrenal glands and the complexity of the adrenal-sympathetic system depends upon the need for the sudden use of energy in attack or escape. This system has therefore reached its highest

development in animals like the lion and tiger, in which there is need for sudden and fierce attack in securing prey, while between the times of attack or escape there is little need for energy as the time is spent in eating and sleeping.

In what way can these facts contribute to a better understanding of peptic ulcer?

The specific action of the adrenal-sympathetic system as we have stated is to inhibit every organ and tissue that is needed for the great muscular activity of the attack or escape. Among the organs most affected therefore are those of the digestive system.

Thousands of years ago in the ancestor of present-day man, we may believe that since his safety depended principally upon muscular attack and escape, the adrenal glands might well have been larger than the thyroid gland. Primitive man attacked, secured his food, escaped to the trees and slept. As the ancestors of man came out of the trees, however, as his hands guided by the developing brain developed new methods of sustenance by tilling the soil and domesticating animals; as the developing brain showed the advantages of co-operation with his neighbours, in times of stress and fear his adrenal-sympathetic system still continued to act as if active physical struggle was required, and therefore the gastro-intestinal tract was inhibited. The physical activities of attack and escape remain among man's racial memories and although the highly developed brain of civilized man has devised religions, laws, customs and systems of education, yet it cannot eradicate the racial memories which are woven in the protoplasmic net of inheritance. It follows that the mechanism by which motor acts are performed and the mechanism by which emotions are expressed are one and the same.

Civilized man is subjected to innumerable actions but much restraint. The more highly civilized the man is, the greater in number are the exciting stimuli, the greater the restraint.

Because of our complicated life, we have many fears—fear of the loss of money and property, fear of moral disgrace, fears as to social status and as to health. Man is beset by fears because of his memory mechanism, a mechanism that has made possible social and economic co-operation. This delicately poised social and economic relation is under constant strain. The driving force of fear and of its lesser form, worry, stimulates human beings to strivings, competitions, rivalries, and jealousies. The greatest and the most constant fear of man is fear of his fellow man. In the world of fears, worries, and anxieties, in which civilized man is engulfed, he fears just as the lower animals fear, largely in the physical terms of his ancestral fight or flight. In consequence, the racial action patterns tyrannize over the remainder of the organism, especially in those individuals who have developed their brains to the greatest degree.

Initiation of action is the function of the special senses and of memory. Although there may be no physical danger, yet, upon receiving an adequate stimulus, racial action patterns throw the switches for full steam ahead, activating the muscles, the adrenals, the thyroid, the heart, the metabolism and the respiration, inhibiting simultaneously the digestive and procreative systems, and as the result of these repeated inhibitions, among other results, indigestion, peptic ulcer and constipation may result. The incidence of peptic ulcer to which we have already referred is evidence of the validity of this reasoning. Other ulcers are constant; peptic ulcer appears in rhythms. Peptic ulcer has not only a rhythm related to the span of life, appearing more commonly in the active young adult period, but it also has a rhythm related to seasons of the year as it appears more often in the spring and autumn. It occurs more frequently in males, the incidence as compared to that in females being as seven to one. Peptic ulcer not only favours the human race and its most advanced members, it not only chooses for its incidence spring and autumn, and the active

period of life, but it is selective even in its victims, as its periods of activity correspond with periods of work, worry, and fatigue.

Peptic ulcer, indigestion, and constipation are aggravated by influences that cause an increase of activity of the sympathetic nervous system such as emotion and focal infection, and is mitigated by influences that lessen the activity of the sympathetic system such as relaxation and holidays. Peptic ulcer is mitigated by any diet or medication that diminishes or neutralizes the acidity and stabilizes the motility of the stomach.

From those considerations it is clear that peptic ulcer itself is an end result; that it is a symptom, and not a separate disease. It is an example of pathologic physiology, not of pathologic anatomy, and the energy or kinetic system of man is the mechanism which is involved in the pathologic physiology which produces a peptic ulcer.

It remains to consider how an ulcer of the stomach is established and maintained in the man in whom there is an over-stimulation of the kinetic system.

Edward Martin and Carlson have shown that the most probable mechanism is the production of a sphincterismus at the pylorus by changes in the activity of certain components of the autonomic nervous system. This sphincterismus causes a break in the perfectly balanced mechanism at the pylorus whereby a balanced acid-alkali relationship is established and the gastric juice, being thus deprived of the alkaline duodenal fluid, rises in acidity and coincidentally the motility of the stomach is greatly increased.

Manifestations of increased activity of the sympathetic nervous system are frequently noted in cases of peptic ulcer, such as increased perspiration, increased nervousness, a tendency to tachycardia, excessive motility, tenseness, excitability, short temper; in other words, many of the general symptoms of mild hyperthyroidism and of mild neurocirculatory asthenia.

Another interesting and significant fact is that the incidence of digestive disturbances in hyperthyroidism is higher than in the normal population. Furthermore, to the high-strung, high-capacity victims of peptic ulcer, as to those suffering from hyperthyroidism or neurocirculatory asthenia, a holiday affords almost a specific relief. These considerations would seem to strengthen the hyperkinetic or neurogenic theory regarding the aetiology of peptic ulcer.

If peptic ulcer is not a morphologic pathology due to exclusively local causes, but, on the contrary, is due to an excessive drive of the sympathetic system, then the administration of a drug, that would counteract the excessive action of the components of the autonomic system, would mitigate the pathologic physiology, namely, the spastic contraction at the pylorus, and relieve the symptoms. This is an established fact.

The seven biologic excitants of the adrenal-sympathetic system are pain, emotion, infection (foreign proteins), hæmorrhage, asphyxia (inhalation anaesthesia), thyroid hormone, and adrenaline. If the kinetic theory as to the causation of peptic ulcer is true, then emotional excitation, infection, pain, thyroid hormone, need be the only biologic excitants to be discussed in a clinical sense. Pain certainly aggravates a peptic ulcer. Emotion and physical exertion are closely related. Both aggravate peptic ulcer, and equally do the toxins of infection. This leaves the thyroid hormone to be discussed. The most outstanding physiologic action of the thyroid hormone is to step up the activity of the brain and the adrenal-sympathetic system, hence emotionalism, hence digestive disturbances. This factor, we believe, is clearly related to peptic ulcer, as we have noted 58 cases in which peptic ulcer has been associated with hyperthyroidism. In these cases thyroidectomy has been followed by a cure not only of the hyperthyroidism but also of the ulcer. Doubtless there were many undetected cases of peptic ulcer among our cases of hyperthyroidism, as x-ray examinations would have revealed, for in hyperthyroidism digestive disturbances

of every kind occur frequently and are taken for granted.

The above considerations offer the clue to the physiologic plan of management. The details vary with the personal equation and the inclination of the physician, and equally those of the patient. In many instances peptic ulcer can be rationalized out of existence. Happily, peptic ulcer passes by the more completely rationalized and controlled men and women who are occupying front line positions in civilization's forward march.

So much for the aetiology of peptic ulcer and other digestive disturbances. In view of this aetiology, what line of treatment is suggested?

The chemical damage due to the accumulation of the injuring gastric juice may be prevented by drawing off the highly acidulated gastric juice by a tube; equally is it prevented by emesis, by lavage, or by alkalies.

The sphincterismus may be relieved by demobilizing the kinetic drive of the brain by a holiday, by apoplexy, by softening of the brain, or by senility.

Although pyloroplasty and gastro-enterostomy, or alkalies, are followed by immediate relief, the patient still is in full possession of the pathologic physiology, which continues to work on its original plan—continues to exercise its pathologic action. For a time after pyloroplasty or gastro-enterostomy, the local sympathetic mechanism at the pylorus, as the result of an activation of which a peptic ulcer was produced, is not reconstructed; but, in time, after either a pyloroplasty or a gastro-enterostomy, the innervation is reconstructed, and, in certain and altogether too many cases, the continuous excessive drive re-establishes the pathologic physiology and the ulcer. This we call a recurrence, but it is a recurrence strictly and only of the ulcer. The pathologic physiology remains unchanged from the first.

This is not equally true of resection of the stomach, for this procedure so extensively destroys the stomach, that the pathologic drive is unable to fabricate an excess amount of ulcer-producing hydrochloric acid and pepsin.

The cases we have been considering are the active ulcers, which usually occur in younger subjects or in the hyperkinetic types of men. The picture is different in individuals of an older, more quiet temperament, and especially in patients in whom obstruction at the pylorus is present. These are mostly cases of healed ulcers. The surgeon in fact operates to relieve the serious complication of a healed, or at least an inactive, ulcer. On the fine results in such cases, much of the good repute of the surgical treatment of ulcer rests.

This brings us to the consideration of an operation devised for the purpose of changing the mechanism whereby the pathologic physiology is produced, an operation performed at a vulnerable point in the adrenal-sympathetic system.

If, as we have argued, this unique disease is due to a long-sustained over-activity of the adrenal-sympathetic system, then a surgical interference with this system should afford a measure of immediate relief and in a period of time a steady improvement, such as follows thyroidectomy in a case of hyperthyroidism.

When there is obstruction at the pylorus, we may assume that a healed or at least an inactive ulcer exists. In this case almost ideal results are secured by a simple gastro-enterostomy. When there is an active non-obstructive ulcer in an active, young, high-strung, worrying individual, then gastro-enterostomy is not indicated, because of the tendency to the formation of recurrent ulcers. Recurrences are more resistant to treatment than is the primary ulcer. The last state is worse than the first. In the case of a recurrent, intractable ulcer in a young individual with a high-strung, worrying temperament, we seek to change the pathologic physiology by denervation of the adrenal glands, otherwise gastric resection is the operation of choice. This procedure is comparable to that employed by Dr. W. M. Scott in surgery of the sympathetic nerves for the relief of mega-colon.

Clinical Trials with a New Antityphoid Serum

By A. FELIX, D.Sc.

(From the *Lancet*, Vol. I, 6th April, 1935, p. 799)

In experiments on mice, published in the *Lancet* last year, it was established that antityphoid sera containing O and Vi antibodies exert two separate and distinct effects, viz:—

(a) The Vi antibody confers protection against infection with highly virulent strains of *B. typhosus*, by suppressing the multiplication of the organisms.

(b) The O antibody appears to be chiefly responsible for effecting the neutralization of the endotoxin of *B. typhosus*.

It was concluded that the efficacy of a therapeutic antityphoid serum would depend on the presence in it of both these antibodies.

Thanks to facilities granted by the Colonial Office and by the Government of Palestine, I have had the opportunity of testing on a number of typhoid patients whether the two effects, established in prophylactic experiments in mice, are demonstrable also in therapeutic trials in man.

Antityphoid sera (nos. 1 and 2) from two horses were used in this investigation. They were prepared in collaboration with Dr. G. F. Petrie and his colleagues at the serum department of the Lister Institute at Elstree. In addition, the serum from a normal horse was used for the treatment of a number of control cases. The antibody content of the sera, determined by agglutination, and the results of protection tests in mice are shown in table I. The details of the mouse protection tests are omitted. The table only indicates

TABLE I

	ANTITYPHOID SERUM		Normal horse serum
	No. 1	No. 2	
Agglutination—			
O titre ..	20,000	40,000	200
Vi titre ..	400 + +	400 +	20 ±
Protection of mice—			
Against infection with live organisms.	+	+	—
Against the toxic effect of dead vaccine.	+	+	—

that the two antityphoid sera possessed both protective power against infection with live organisms and neutralizing power against the toxic effect of a dead vaccine of *B. typhosus*. Normal horse serum had no effect in either of these capacities.

NATURE OF THE TRIALS

The three sera were used unconcentrated and the standard dose for adult patients was 50 c.cm. administered by the intramuscular route. In severe to very severe cases this dose was given on three consecutive days—i.e., a total of 150 c.cm. of serum was injected intramuscularly. In cases of extreme severity (patients actually moribund or in a desperate condition) the serum was administered intravenously, again employing 50 c.cm. as the routine dose, which was repeated twice or three times at intervals of 24 hours, making a total of 150 c.cm. or 200 c.cm. per case. According to the history as regards previous serum treatment the intravenous injections were either given without particular precautions or the patients were desensitized by injecting first 0.1, 0.2 and 0.5 c.cm. at intervals of half an hour and then the full dose of 50 c.cm.

The total number of typhoid patients treated in Palestine during October and November of last year and the routes of administration of the serum are shown in table II. The table shows that most patients were

TABLE II

	PATIENTS TREATED WITH—	
	Antityphoid serum	Normal horse serum
Intramuscularly ..	32	14
Intravenously ..	10	3
Intrathecally ..	1	..
TOTAL ..	43	17
(Children below 14 years) ..	[6]	[3]

adults. Only 9 of the 60 patients were children below fourteen years. The dosage for children was according to the following scheme:

Children below 5 years	10 c.cm.
" 6—9 "	20 "
" 10—14 "	30 "
" over 15 "	* 50 "

* Full dose for adults.

It is further seen from the table that the number of control cases, treated with the normal horse serum, was much smaller than that of the patients treated with antityphoid serum. As soon as the difference between the results following the injections of the two types of serum became evident, the physicians in charge of the patients could not be induced to continue the use of the control serum.

The patients were not subjected to the treatment indiscriminately. They were selected with a view to excluding mild cases and those of moderate severity. The procedure was to class each case before the beginning of the serum treatment under the headings 'severity of toxemia' and 'severity of pyrexia', and from these two criteria the 'total severity' was derived. After the injections the 'effect on toxemia' and the 'effect on pyrexia' was assessed and recorded separately.

The great majority of the patients came from the Jaffa-Telaviv district where the incidence of typhoid fever was still high during October and November 1934. Table III gives the exact figures.

TABLE III

Locality	Hospital	Physicians in charge	PATIENTS TREATED WITH—	
			Antityphoid serum	Normal horse serum.
Jaffa	Govt. Hosp.	Dr. R. Reitler	25	9
Telaviv	Municipal Hosp., 'Hadassah'	Drs. M. Levontin and W. N. Wolff.	12	4
Jerusalem	Govt. Hosp.	Dr. N. Hamzeh	3	4
Do.	German Deaconess Hosp.	Dr. N. T. Canaan	3	0
TOTAL	43	17

Uniformity in classifying the cases with regard to their severity was assured by the fact that 50 patients out of a total of 60 were treated in two hospitals under the care of physicians with particular experience of typhoid fever. It was also facilitated by the fact that in most cases the serum treatment was begun during the second or third week of the illness with the symptoms of disease fully developed. The relevant data are recorded in table IV.

TABLE IV

Serum treatment commenced during—	PATIENTS TREATED WITH—	
	Antityphoid serum	Normal horse serum
First week	7	1
Second „	25	12
Third „	6	3
Later than third week ..	5	1
TOTAL ..	43	17

RESULTS

The results of the serum treatment observed in the 17 control cases can be dealt with very briefly. Following the intramuscular or intravenous injections of normal horse serum there was in no instance any change in the toxæmic symptoms of the patients. In some cases the fever was lowered, but this effect was only temporary, and after a few days the temperature rose again. The general condition of most of the patients treated with normal serum was rather worse than it had been before, and this caused the physicians to discontinue its use early in the course of the investigation.

The effects of the treatment with the two antityphoid sera, on the other hand, were quite different. To avoid reproduction of a considerable number of individual case-charts I have attempted to summarize the results in table V. It is seen that the series of 43 cases treated with antityphoid serum includes only 1 case classed as 'mild' and 9 of 'moderate severity', whereas 21 cases are designated as 'severe or very severe', and 12 as 'extremely severe'. The last group is composed of patients whose condition before the commencement of the serum treatment was considered as desperate or who were actually moribund.

TABLE V

Effects of treatment with antityphoid sera nos. 1 and 2

Clinical course	Cases treated	EFFECT ON—				Died
		Toxæmia		Pyrexia		
		+	—	+	—	
Mild ..	1	0	0	1	0	0
Moderately severe	9	3	0	6	3	0
Severe or very severe.	21	15	3	11	10	0
Extremely severe	12	6	6	5	7	5
TOTAL ..	43	24	9	23	20	5

It has been mentioned above that each case was classed separately under the headings 'severity of toxæmia' and 'severity of pyrexia', and that a 'total severity' was derived from these two criteria. For the sake of simplicity this 'total severity' alone is indicated in the first column of table V, whereas 'effect on toxæmia' and 'effect on pyrexia' are recorded separately. The symbol + denotes a marked favourable effect, and — indicates that there was no effect. In each subgroup the sum of the two figures recorded under the heading 'effect on pyrexia' is equal to the total number of cases treated. Under the heading 'effect on toxæmia', however, the sum of the two figures is, in the first three subgroups, smaller than the corresponding total number; the difference indicates the number of cases without marked toxic symptoms.

Table V shows that the effect on the toxic symptoms was stronger and more regular than that on the fever. Out of the total of 43 cases, 33 had definite toxic symptoms of varying degrees up to complete stupor and severest status typhosus. Of these 9 cases only remained uninfluenced by the serum treatment, whereas in 24 cases the toxic symptoms ceased, usually after the second or third dose of serum, and did not reappear. On the other hand, the fever was clearly shortened and definitely suppressed only in 23 cases, whereas 20 remained either entirely uninfluenced or showed merely temporary lowering of the fever, similar to that observed in the control group of cases treated with normal serum.

When the different subgroups in table V are considered separately, it is seen that with the increasing severity the numbers of failures increase under both headings. This finally led to the application of the intravenous route instead of the intramuscular injections which had been used throughout the greater part of the trial. The effect both on the toxæmic symptoms and on the fever was very much stronger following intravenous administration. However, it will be remembered from table II that only 10 of the 43 patients recorded in table V received intravenous injections, whereas 32 were treated by the intramuscular route.

To give an indication of the powerful antitoxic action of the immune serum it may be mentioned that in some instances two or three injections, given intramuscularly or intravenously at intervals of 24 hours, transformed a condition of complete unconsciousness into one of well-being. This effect was most striking in a number of patients whose toxic symptoms disappeared while the fever still continued unabated. The condition sharply contrasted with that observed in some of the patients of the control group, where the non-specific action of the normal serum resulted in a temporary lowering of the fever with the toxic symptoms left entirely undiminished.

It is not possible, without reproducing individual case-charts, to discuss the results in greater detail. The small number of cases treated also does not permit of any calculation of a reduction in the death rate or in the duration of the fever period. All that can be stated is that a number of patients were justifiably considered as having been saved by the serum treatment, while in a number of less gravely ill patients the fever period was considerably shortened.

Two unusual cases seem worthy of being mentioned specifically. Both patients were treated by Dr. R. Reitler at the Government Hospital, Jaffa.

A woman of 32 developed on the twenty-third day of her typhoid fever meningitic symptoms and severest status typhosus. Lumbar puncture revealed clear fluid under high pressure; 70 c.cm. of fluid was removed and 40 c.cm. of antityphoid serum injected intrathecally, and there was slight improvement. The same procedure was repeated 48 hours later and resulted in definite recovery. The patient was discharged from hospital 14 days after the second injection of serum.

The second case was one of perforation of a typhoid ulcer in a male patient of 20, who left his bed in a semi-conscious condition on the fourteenth day of the

disease. Dr. W. E. Thompson, surgeon specialist to the Department of Health, Jerusalem, operated on the patient about 18 hours after the perforation had occurred and administered 80 c.cm. of antityphoid serum directly into the peritoneum. The patient also received 50 c.cm. of the serum by the intramuscular route. He recovered, and the surgeon attributed this to the effect of the serum treatment.

There can be little doubt that the antitoxic activity of the serum is due to the O antibody. The serum no. 2 (see table I) with an O titre of 1 in 40,000 acted more strongly on the toxic symptoms than the serum no. 1 with an O titre of 1 in 20,000. To what extent the suppression of the fever is to be attributed to the action of the Vi antibody cannot be answered from the present trial, since there was no control group of cases treated with a serum containing O antibody alone. Assuming that pyrexia is an expression of the multiplication of the invading organisms with consequent production of toxin, we would conclude from the protection experiments in mice with Vi antibody alone that the effect of the latter in suppressing invasion would be most clearly manifested by the degree of fever in the earlier stages of enteric and in relapses. The earlier therefore the case comes under treatment the greater should be the opportunity for the Vi antibody to exercise the invasion-suppressing function so clearly exhibited in the mouse experiments. It is proposed in future clinical trials to compare a pure anti-O serum with the serum we have been discussing, containing both O and Vi antibodies.

However, the main object of the present investigation was to establish in therapeutic trials in man whether or not some action on the toxic symptoms and on the fever was exercised by the antityphoid serum. It would appear that the answer to this question is in the affirmative.

Aural Complications of Influenza

By JOHN F. O'MALLEY, F.R.C.S.

(Abstracted from the *Medical Press and Circular*, 27th March, 1935, Vol. CXV, p. 303)

Every outbreak of influenza is responsible for a certain proportion of aural complications, ranging in severity from a simple inflammation of the Eustachian tube or middle ear, to suppuration of the latter, a mastoiditis, or even a lateral sinus thrombosis. One sometimes wonders that the incidence is not much greater when we come to consider the intimate physiological relationship which exists between all the air cavities that open into the upper respiratory tract.

It will be profitable here to make a brief digression to examine some of these activities, to enable us to understand more readily how the health is maintained and why the intrusion of an acute inflammatory infection is bound by its reactions to impair this; and, further, it will make the principle which should underlie treatment appear more obvious and logical.

The middle-ear cavity is an air space, functioning most of its time at atmospheric pressure level, and subject to the entrance and withdrawal of air through the Eustachian tube. This air movement does not synchronize with every respiratory act of the nose and lungs, as it does, for instance, in the maxillary and other accessory sinuses, because we find that the pressure of air in the antrum and nose is lower than that of the atmosphere during inspiration, and higher on expiration. During the act of swallowing the air pressure in the pharynx can be shown to be at the atmospheric level, and every performance of this act partially opens the Eustachian tube, whose V-shaped orifice is directed downwards (possibly purposeful), and thus an equal pressure on both sides of the tympanic membrane can be easily maintained. Attempts at

inspiration with the anterior nares occluded withdraw air from the middle-ear cavity, reducing the pressure inside the membrane below that of the atmosphere on its outer surface. Attempts at expiration under similar conditions will increase the pressure in the tympanum above that of the atmosphere. The exercise of the latter procedure, as applied to treatment, is known as the 'method of Valsalva', and the same principle underlies the method known as 'politzerization'.

I must not delay here to dwell on the activity of cilia, mucin, and other secretory functions, air humidification, etc., all of which may be comprehensively regarded as a mechanism provided for the purification and sterilization of the air which enters the nose and sinuses before it passes for oxygenation to the lungs, further than to state that this appears to be carried on efficiently, so long as the varying air-pressure movements mentioned above remain possible. These movements I have referred to elsewhere under the term 'ventilation'.

Bearing this in mind, it will now become obvious that the invasion of the upper airway by an infective inflammatory process with its reactions, and especially if of the type seen during epidemics of influenza, must very seriously, if not at times completely, impair these ventilation movements, and it is thus that the middle-ear cavity may become involved.

Some confusion may arise in the reader's mind when he studies so many apparently isolated phenomena as presented in the literature on air-cavity infections, unless he understands the principle which underlies their ventilation. I would like therefore to emphasize the fact that there is no peculiar mystery about the biological phenomena of inflammation in the nose and its adjoining air spaces, when compared with those seen in any solid organ or hollow viscus of the body, because they are essentially identical and go through the same phases of development and resolution or suppuration; but its reactions here assume a special character, which is entirely conditioned by their power or not to maintain their allotted air function in the respiratory tract.

Following inflammatory subsidence, the normal type of nose is rapidly restored to its relative air patency owing to the establishment of its through-and-through ventilation currents, causing the removal of all gross exudates, but this desirable result is not so easily obtained in recessed cavities.

The Eustachian tube projects somewhat like a nipple into the nasopharynx with its V-shaped orifice downwards, an anatomical arrangement which possibly protects its lumen in some measure from the spread of inflammation by continuity, but it is liable to get infected by a 'droplet method' with any violent expiratory efforts, such as sneezing in the earlier part of an influenza attack, or, later, from blowing the nose in the exudative stage of the nasal inflammation.

The middle-ear space regarded as a recessed air cavity, removed from the common respiratory tract by a long narrow channel (especially in the adult), and only intermittently in air continuity with it, derives from this anatomical design a considerable measure of protection against air-borne infections, which possibly explains why it escapes many of the simpler invasions of the upper airway, and is only involved by some of the more virulent.

But once invaded by a severe inflammatory process, which fully develops to an exudative stage, the protective design against the entrance of infection becomes now a source of embarrassment, preventing free ventilation, and with it the removal of secretions, so that yielding of the tympanic membrane to the pressure of these exudates, or their release by surgical means, becomes the only safety valve for their escape. The middle ear may be infected almost simultaneously with that of the upper airway, but, as I have pointed

out elsewhere, it is more prone to occur later in the attack, when free exudates are present in the nose, and the patient tries to remove them by forced expiratory efforts.

I have personally seen some cases where the ear complications were very severe, if the infection began early or co-incidental with the influenzal attack, as contrasted with some which arose at a later stage. Possibly in the latter the nasal attack had already conferred some immunity, which raised the resistance in the middle ear.

Remarks.—Apart from influenzal infections, a primary acute middle-ear suppuration is rare in adults. Its incidence in childhood and adolescence is considerable, and the tendency to extensions beyond the middle ear equally so. This incidence, however, is not so great in my experience, as that accompanying the exanthemata; but the contrary is true of adults, the possible explanation of this being the presence of adenoids in children and their absence with a well ventilated nose in the adult. It is also noteworthy that persons who have frank intra-nasal suppurations, such as ethmoiditis or atrophic rhinitis, are apparently less prone to acute otitis media during these epidemics than those with previously clean noses. It is thought that a localized tissue immunity has resulted here from the chronic sepsis.

Symptoms.—These are necessarily general and local: the former, such as pyrexia, increase of pulse rate and malaise, arise from a systemic reaction to inflammation in the common upper respiratory tract, and now extending to, or present in, one of its adjoining spaces. The local symptoms naturally involve impairment of ear function. Pain is an outstanding symptom, due to engorgement of the lining in a limited air space, and this is accompanied by increasing deafness and pyrexia. As the case progresses towards suppuration, inflammatory exudates tend to accumulate in the cavity, and as no escape is now possible through a swollen Eustachian tube, distension takes place at the expense of the only mobile wall, the tympanic membrane, and so the pain increases, and may become excruciating. It is boring and throbbing in character, the throbs corresponding to the heart beats.

An early hæmorrhagic discharge, which is in reality a blood-stained serum, occurring with the onset of earache, is almost pathognomonic of an influenzal infection of the *Streptococcus hæmolyticus* type. This is not, however, any evidence of a perforation of the drum.

Treatment.—This should be general and local. Every available means of abating the severity and duration of the inflammatory attack should be resorted to, in the hope of limiting its extension and possible complications. Bed and an equable room temperature are of the first importance to soothe the invaded respiratory tract.

Free perspiration for twenty-four to forty-eight hours is invaluable, the merits of which I have frequently tested. The vaso-dilatation associated with this relieves the inflammatory tension and pain, and promotes sleep and the elimination of toxins. The arms should be kept under the bedclothes. A preliminary bath, as hot as bearable, for two or three minutes will cause cutaneous redness and start vaso-dilatation. This action is aided by an occasional dose of such drugs as aspirin and soda salicyl. with a fairly abundant intake of fluids, and either warm or cold water, as the patient may fancy. Underclothing which does not chill the skin when wet, and which can be changed safely when it is so, is essential if this method is adopted, and for this reason wool or a large admixture of it is indicated. Free action of the bowels is desirable. Start with calomel, gr. $\frac{1}{3}$, at night, followed by a saline next morning.

An injection of 10 cubic centimetres of anti-scarlet fever serum (concentrated streptococcus anti-toxin, scarlatina. B. W. & Co.) early in the attack exercises a beneficial influence over its progress. I am more favourably impressed by its action than that of S. U. P., which I

used formerly. Another 10 cubic centimetres can be given in twenty-four hours.

Local treatment of the nose and ear.—I am averse to any liquid treatment of the nose or airway in the acute stage. Steam vapours, medicated with tincture benzoin compound or menthol, may be inhaled, and are soothing. Wearing a light gauze mask over the nose and mouth for a great part of the twenty-four hours is very comforting, as it allays the tendency to sneezing and coughing, and therefore has the further advantage of limiting the dissemination of infection. In the early stage of earache with slight deafness and pyrexia, and only redness of the membrane, expectant treatment may prove effective, as many such cases arise which never proceed beyond this phase, but which if surgically incised must suppurate, no matter how aseptically the operation is performed.

Two or three per cent of glycerine acid carbolic dropped twice daily into the ear renders the meatal passage is a condition to be desired in the event of a sudden or unexpected perforation of the membrane occurring, or surgical incision of it becoming necessary.

If the pain, deafness and pyrexia continue or increase the case is now passing to the exudative stage, and will end in suppuration. An examination of the membrane by anyone possessing the necessary skill and experience will reveal œdema and bulging. If these are present, release of tension by surgical means is indicated. Spontaneous perforation or simple puncture will answer the physiological needs for the relief of tension and pain, but they may fail to permit a sufficiently free escape of the inflammatory products, which is essential to the quick return of the cavity to its air-containing function.

A long of the membrane is being then high in gauze, left in for two days, to be followed by the daily introduction of boric powder iodized to 1 per cent. Avoid damming up the external meatus, and the return of middle-ear ventilation via the Eustachian will soon prove an effective factor in drainage.

Favourite Prescriptions: The Pharmacopœia of the Middlesex Hospital

By E. A. COCKAYNE, D.M., F.R.C.P.

(Abstracted from the *Practitioner*, Vol. CXXXIV, May 1935, p. 685)

Among the formulæ for general use there are a number of *aperients*, but only one differs appreciably from those to be found in the pharmacopœias of other large hospitals. This is the emulsion of liquid paraffin which, owing to the reduced content of gum, is much thinner than most emulsions of paraffin and is therefore easier to dispense and more pleasant to drink. It acts well and patients do not complain of the leakage of oil, which is so often troublesome when pure paraffin is taken.

R Paraffini liquidi	4 fluid ounce
Pulveris acaciæ	20 grains
Sodii benzonitis	1 grain
Sodii chloridi	1 "
Vanillini	1/80 "
Glusidi	1/80 "
Aquam ad	1 fluid ounce

Formulæ for diseases of the alimentary tract.—One of the prescriptions most frequently dispensed to out-patients is the alkaline gentian mixture:—

R Sodii bicarbonatis	10 grains
Tincturæ zingiberis mitis	10 minims
Tincturæ rhei compositæ	3 "
Spiritus chloroformi	5 "
Infusum gentianæ ad	1 fluid ounce

Another popular mixture designed for the treatment of flatulent dyspepsia has remained unchanged for at least thirty years:—

R Sodii bicarbonatis ..	10 grains
Spiritus ammoniæ aromatici ..	20 minims
Spiritus chloroformi ..	10 "
Infusum caryophylli recens ad ..	1 fluid ounce

The modern treatment of peptic ulcer by means of large doses of alkalis is reflected by the presence of two powders containing the light and heavy carbonates of magnesium and chalk, but in different proportions. The old powder containing bismuth and the carbonates of magnesium has been retained and the following new one has been added:—

R Kaolini ..	20 grains
Magnesi carbonatis levis ..	20 "
Magnesi carbonatis ponderosi ..	20 "

The kaolin is not only cheaper, but probably has an additional value as an absorbent of toxins.

The *Haustus cretæ* compound of 1899 is now made up with chloroform water instead of distilled water, and is as follows:—

R Cretæ preparatæ ..	15 grains
Mucilaginis acaciæ ..	60 minims
Tincturæ catechu ..	20 "
Aquam chloroformi ad ..	1 fluid ounce

It is a useful formula for diarrhoea.

Both valerian and asafoetida are reputed to be carminatives, but the continued presence in the pharmacopœia of a mixture containing both of them is due rather to their nauseous taste than to their pharmacological action. The mixture is retained to satisfy the patients who think that the stronger the smell and the more unpleasant the taste, the greater must be the efficacy of a medicine. Its value is considerable, if it is used with discretion, and, strangely enough, it is popular with the patients.

R Tincturæ valerianæ ammoniatæ ..	20 minims
Tincturæ asafoetidæ ..	20 "
Infusum quassia recens ad ..	1 fluid ounce

Cough mixtures.—The *Haustus ipecacuanhæ* cum ammonia has its counterpart in most hospital pharmacopœias and is a useful expectorant mixture, while the *Haustus ipecacuanhæ* compound is both sedative and expectorant. Though its ingredients might be thought to neutralize each other, the clinical experience of more than one generation of physicians has proved its value. It is given for acute bronchitis and is as follows:—

R Tincturæ ipecacuanhæ ..	10 minims
Tincturæ opii camphoratæ ..	30 "
Liquoris ammonii acetatis fortis ..	30 "
Aquam ad ..	1 fluid ounce

For the early stage of acute bronchitis, when there is congestion of the mucous membrane and the cough is dry, the mixture which was added to the pharmacopœia on the recommendation of the late Sir James Kingston Fowler, the *Haustus sodii chloridi* compound, sometimes gives relief. It is as follows:—

R Sodii chloridi ..	5 grains
Sodii bicarbonatis ..	5 "
Spiritus chloroformi ..	5 minims
Aquam cari ad ..	1 fluid ounce

A useful expectorant mixture for chronic bronchitis is the *Haustus senegæ* compound:—

R Ammonii carbonatis ..	3 grains
Tincturæ scillæ ..	20 minims
Olei pimentæ ..	1 minim
Spiritus chloroformi ..	10 minims
Infusum senegæ recens ad ..	1 fluid ounce

The fresh infusion prevents the formation of a deposit in the mixture.

The *Haustus potassii iodidi cum stramonio* is designed for the treatment of asthmatic patients in the intervals between their attacks or in chronic bronchitis, when the cough is spasmodic. It contains:—

R Potassii iodidi ..	3 grains
Tincturæ stramonii ..	15 minims
Extracti glycyrrhizæ liquidi ..	20 "
Aquam chloroformi ad ..	1 fluid ounce

In asthma the amount of stramonium should be increased until it causes dryness of the mouth, and then reduced, until this effect is no longer troublesome, and this, which is the optimum dose for the individual, should be continued. Though the mixture has been dispensed unofficially for a long time, it appeared officially for the first time in the 1933 edition.

For an irritating cough there is the *Linctus pectoralis*, which is similar in composition to Ger's linctus, a preparation often dispensed, but never incorporated in the pharmacopœia. The formula for the *Linctus pectoralis* is:—

R Oxymellis scillæ ..	10 minims
Tincturæ opii camphoratæ ..	10 "
Spiritus ætheris nitrosi ..	5 "
Aquam ad ..	60 "

Urinary antiseptics and diuretics.—The usual mixture containing both hexamine and acid sodium phosphate, which is in use in most of the large hospitals, is unsatisfactory owing to its gradual decomposition with the liberation of formaldehyde. The Middlesex is one of the few hospitals which dispenses the two chief ingredients separately with the direction that half an ounce of each solution should be mixed immediately before being taken:—

R Hexaminæ ..	10 grains
Tincturæ hyoscyami ..	30 minims
Infusum buchu recens ad ..	1 fluid ounce

R Sodii phosphatis acidii ..	20 grains
Infusum buchu recens ad ..	1 fluid ounce

For pyelitis there is a mixture containing 30 grains of potassium citrate, a more alkaline mixture made by the addition of 30 grains of sodium bicarbonate, and a third to which 30 minims of tincture of hyoscyamus has been added for use, when pain is severe.

There are no formulae containing a diuretic acting directly on the renal cells, though prescriptions with one or other of them as an ingredient are in regular use. It is with regret that one notices the omission of the old *Haustus scoparii* from the 1933 edition:—

R Potassii acetatis ..	20 grains
Tincturæ scillæ ..	10 minims
Spiritus ætheris nitrosi ..	30 "
Infusum scoparii ad ..	1 fluid ounce

It sometimes gave satisfactory results, when the remedies in commoner use had failed, but its already limited sphere of usefulness has been encroached upon by the newer and more active proprietary compounds of mercury, such as salyrgan.

Medicines for special diseases.—When gout was still common there was a *Haustus potassii iodidi cum colchico*, but this was omitted in the edition of 1915. In the last edition a new prescription has been introduced without potassium iodide and with the tincture instead of the obsolete vinum colchici. This is:—

R Tincturæ colchici ..	10 minims
Potassii citratis ..	20 grains
Magnesi sulphatis ..	20 "
Infusum buchu recens ad ..	1 fluid ounce

Another disease the incidence of which has changed very greatly since 1915 is encephalitis lethargica. This became common in 1918, and a prescription has been

inserted in the last edition for the treatment of its sequelæ.

R Hyoscine hydrobromidii	..	1/100 grain
Tincturæ lavandulæ compositæ	..	5 minims
Aquam chloroformi ad	..	1 fluid ounce

The modern treatment of thyrotoxicosis has led to the addition of *Haustus iodi*, which contains 0.06 gramme of free iodine in each ounce:—

R Liquoris iodi mitis	..	41½ minims
Aquam ad	..	1 fluid ounce

This preparation, which, unlike the more familiar Lugol's solution, contains no potassium iodide, is most often used for preparing patients for partial thyroidectomy, and its effects are determined by estimations of the basal metabolic rate.

Recent work has proved that much larger doses of iron are often needed for the cure of anæmias than were formerly considered to be necessary, and this is particularly true of the hypochromic microcytic anæmias of middle-aged women. This change of practice has induced the compilers of the pharmacopœia to increase the strength of the *Haustus ferri et ammonii citratis*, and it now contains 20 grains of iron and ammonium citrate instead of 5 grains to the ounce, a dose which had remained unchanged for more than 30 years.

One more preparation from the general formulæ may be selected for mention. The *Collutorium phenolis cum iodo* is a valuable antiseptic mouth wash for use after the extraction of teeth:—

R Phenolis liquefacti	..	30 minims
Liquoris iodi mitis	..	15 "
Aquam ad	..	1 fluid ounce

One teaspoonful to half a tumblerful of water.

The special departments have their own preparations, those for the Children's Department being called *misturæ* to distinguish them from the *Haustus*. Although their number has been increased greatly in the last two editions, most of the old formulæ have been discarded and the new ones have been borrowed from sources outside the hospital.

From the preparations in use in the Ear, Nose, and Throat Department, the *Nebula camphoræ composita* may be selected for mention:—

R Camphoræ	..	3 grains
Mentholi	..	3 "
Guaiacoli	..	3 minims
Olei cinnamoni	..	1 minim
Paraffinum liquidum ad	..	1 fluid ounce

This makes an agreeable nasal spray and used for many inflammatory conditions of the nose.

The Eye Department has a large number of formulæ from which two are selected. The *Oculentum ichthammolis cum zinci oxido*:—

R Ichthammolis	..	1 per cent
Zinci oxidi	..	15 "
Paraffinum molle flavum ad	..	100 "

For chronic blepharitis; and the *Guttæ hyoscine*:—

R Hyoscine hydrobromidi	..	0.25 per cent
Chlorbutolis	..	0.3 "
Aquam distillatum ad	..	100 "

a mydriatic used when atropin causes irritation. The addition of chlorbutol makes this superior to the hyoscine drops in use at some of the other large hospitals.

From the formulæ for use in the Skin Department it is difficult to single out one more worthy of mention than another. The value of magnesium sulphate for the treatment of boils has been recognized officially, and the *Pasta magnesi sulphatis* has been included for the first time in the 1933 edition:—

R Magnesi sulphatis exsiccati	..	360 grains
Glycerini	..	180 minims

Bacillary Dysentery: A Summary of Treatment With Brief Statistics of an Epidemic

By H. W. CORNER, M.D.

(Abstracted from the *British Medical Journal*, Vol. I, 8th June, 1935, p. 1162)

THEORETICAL CONSIDERATIONS

THE toxæmia, and the orderly sequence in clinical events following infection, serve to distinguish bacillary dysentery from the many miscellaneous causes of this unpleasant symptom. When an exotoxin is present, as with the Shiga bacillus, the effect appears early and is severe. The amœbic disease has none of these general features. It may acquire high endemicity, but cannot become epidemic. The morbid process differs, and the course of disease is necessarily distinct.

The degree of severity in bacillary dysentery is the basis of clinical classification, the disease being either (1) mild, (2) severe, or (3) fulminating (choleraic): serum treatment is indicated in all except the mild cases. Clinical judgment depends on a recognition of underlying mechanisms. For example, in the Shiga infection there is early histotoxic anoxæmia, often manifest in the patient as a peculiar bluish flush, and giving way sooner or later to pallor. There is loss of tone in capillary and vasomotor areas, and a resulting fall in blood pressure. The signs denoting severity are those of imminent collapse, and are in terms of the circulatory system; they are not of the arresting nature of tenesmus or of strangury, and need not occur in proportion to the degree of fever or the frequency of stool. Bacillary dysentery is more than 'an abdominal disease'. It is for this reason that many cases which begin mildly become later severe or fatal.

Early exhaustion, which is due to toxæmia, is amenable to treatment, and certain drugs are of some value. Late exhaustion results from tissue depletion. It is less amenable to treatment, and all drugs are useless. It should not, however, be considered an inevitable and vague state of dissolution. To toxæmia is added deprivation and loss of most of the pabulum out of which biochemical balance is effected. The mechanism of the syncope is that of peripheral circulatory failure. The principles of treatment are therefore as follows: improvement of tissue nutrition; increase of blood volume in terms of venous return; conservation of body fluids and of body heat; and conservation of energy, especially in the posture and effort of defæcation, or in the distress of incontinence.

Necrosis or ulceration of the colon is a lesion entailing certain difficulties in treatment. The necrosis is superficial, but cellular reaction in the underlying layers may be severe. In the peritoneum this reaction is usually negligible, but occasionally may be severe enough to cause death. There is general thickening of the bowel—often from cæcum to rectum—into the semblance of a tube of chewed leather, lined by dark green blood-and-bile-stained shaggy coagulum. This is a lesion for which it is useless to continue pouring down salines by mouth. The position should be considered. The bowel, upper and lower, has been emptied by an initial purge, serum has been administered, and toxæmia is therefore no longer a danger. The patient's diet has for several days consisted of fluids. The over-persistent use of salines will now cause elimination or excretion of nothing but valuable nutritive fluid, will aggravate hypotension, and will precipitate collapse. Even the injunction 'salines four-hourly till the stools become fæculent' may be dangerous advice.

It would be unwise, moreover, to attempt per-rectal irrigation of the ulcerated area with antiseptic solutions of a strength whereby absorption would be toxic, or of a nature whereby too astringent an effect would be equally undesirable. Local administration of such solution can produce harm more readily than good. The sole purpose of irrigation should be the removal of

irritation from debris accumulated within the lumen of the bowel or on the surface of the lesion.

TREATMENT IN PRACTICE

The castor oil and opium purge is a sound preliminary, but is unsuitable for patients who, when first seen, have already spent two or more miserable days of diarrhoea. It is a special benefit when there is more early colic than early diarrhoea. It is too valuable to be omitted just because the laboratory requires specimens without oil; specimens can always be had before the oil is given.

USE OF SERUM

Given early, serum is the most effective single therapeutic measure in this disease. It should be given promptly in every severe case of epidemic dysentery without waiting for bacteriological reports on cultures. Specimens are plentiful. Macroscopic and microscopical examination of faeces should be done as part of the 'condition on admission'. There is sufficient evidence at hand for immediate decision. Exactitude of dosage and route of administration matter less than that the serum should be given promptly. The initial dose should be 40 to 80 c.c.m., repeated if necessary on the following day. The intramuscular route is the method of preference.

It is well to remember that bacillary dysentery is a disease 'at first worse than it seems and later as bad as it looks'. There is a type of patient who suffers quietly and uncomplainingly for a few days, and subsequently becomes alarmingly collapsed during a period of relaxed observation. Pallor, frequent and small-volume pulse, and systolic blood pressure under 90 mm. Hg. are then discovered for the first time. It is the management of this type of case that often decides whether the mortality figure for an epidemic is to be high or low. It might be said that the very worst cases succumb in spite of treatment; the very mild cases recover irrespective of treatment; the cases initially severe receive prompt treatment and so recover; but the cases beginning in a mild way and later becoming severe miss the benefit of early serum and so tend to run a more precarious course.

Concerning the customary guides to severity—namely, fever and frequency of defaecation—three things should be kept in mind. (a) That the time of examination may happen to be at any point in the rapid sequence of fever (subnormal \rightarrow continued \rightarrow remittent \rightarrow irregular \rightarrow normal), or in a similar and roughly corresponding sequence in the stools (diarrhoeal \rightarrow mucosanguineous \rightarrow 'ulcerative type' \rightarrow sanguino-faeculent \rightarrow semi-formed). (b) Although the above order is usual in Shiga infection there may be any variation. (c) In the worst type of case the patient has neither fever nor time for defaecation.

The serum is antibacterial as well as antitoxic. It is perhaps for this reason, or because of the benefit accruing from the globulins, that serum given late in the disease, though less effective than when given early, nevertheless produces undoubted improvement. Such use, however, implies a failure in early diagnosis or a failure in the estimation of degree of severity.

Bacteriophage has much in the nature of its inception to justify great expectations in dysentery. Nevertheless its failure is such that its use in treatment may amount to dangerous experiment. It proscribes the use of serum, and suspends other treatment with no appreciable benefit and with the risk that such omission entails. With its *in vitro* success and its *in vivo* failure this substance would appear to have been introduced prematurely into therapeutics.

SALINES AND DIET

Sodium sulphate in mixture (5 j to fl. \bar{x} j) is stock treatment, but the routine scheme should be varied for the individual. When an initial purge has been given,

one ounce of the mixture should be administered two-hourly for one day, four-hourly for the next two or three days, and then dropped, as soon as possible, to a single early morning dose. When no initial purge is given, hourly doses for eight hours can be used during the first day, two-hourly the second day, four-hourly on the day following, and can be suitably tapered off. There can be no fixed rule; pulse, blood pressure, nature of stool—all have to be considered.

Diet is all-important. The dictum 'fluids and plenty of them' refers not to the diet itself but to the simple flavoured drink which should be present in a jug by the bedside and duly replenished. Milk should never be given, either fresh, diluted, or disguised, for it induces colic and an aggravation of abdominal symptoms. Occasional ice-cream has no contra-indication. Chicken tea, arrowroot, beef tea, and ... mentioned in the order in which ... of value, and, incidentally, in the patient's order of preference. The laxative effect of meat extracts is to be remembered. Rigorous mouth hygiene is important, and chewing gum is both useful and comforting.

This two-hourly dietary, varied suitably but not over-stepped, serves to tide the patient over his initial toxæmia, but it should not be prolonged unnecessarily. There should be a gradual increase to custard; tea, with an egg and thin bread-and-butter; steamed fish; minced chicken; milk puddings (except rice); and mashed potato. There will be intolerance of certain foods or temporary discomfort following others, but these are not signs for a return to fluids. Likewise it is well to note, but not to be alarmed at, some traces of blood reappearing in the stools.

The diet in late marasmus requires separate consideration. Here the emaciation is extreme. The body weight of an adult male may drop under 4 stone. The patient's appearance may suggest a skeleton or a shadow, and is a spectacle of the horror of disease. There is fretful childishness as well as pitiful enfeeblement. This is a condition requiring light but highly nutritious diet of a wide range, with vitamin preparations given with a definite purpose in view and not haphazard. A nursing staff with infinite patience and a tactful cajolery is as necessary as a suitable diet. A remarkable feature of this condition is the degree of emaciation and the duration of this precarious vegetative state that is compatible with complete recovery.

RELIEF OF PAIN

This is a necessity in every case. In the treatment of this disease there is no place for morphine. Opium itself, however, in the form of the tincture, has its limited use at first with the purge, and occasionally later, but before exhaustion sets in. Hypodermic preparations of the total alkaloids of opium do not appear to have all the dangers of morphine alone, and, suitably restricted, are permissible in emergency. The pain of tenesmus may be relieved by hot water rectal irrigation. Anal pain is relieved by atropine in suppository. Prolapse and hemorrhoids, old and recent, are temporarily relieved by local bathing with hot water, thorough drying, and subsequent application of the non-aqueous calamine cream to the skin. The pain of strangury is relieved by belladonna in alkaline mixture in suitably large doses. The general abdominal discomfort is made easier, when practicable, by radiant heat. The pain of iritis will be mentioned later.

INTRAVENOUS MEDICATION

This is called for in every severe case. It is used early in toxæmia for serum, when the necessity for the latter would appear too urgent for intramuscular injection, and early in exhaustion for 5 per cent glucose in normal saline. The time-indication for glucose in saline is important. If left too late the therapeutic opportunity is lost. Moreover, venous collapse is not just a

There are then three extremely useful chapters on the principles and practice of hæmatological diagnosis; in these technique is not included, but a separate chapter of about 50 pages is devoted to this subject and is suitably placed at the end of the book. This chapter on technique enhances the value of the book very considerably. Again the exigencies of space have limited its scope, but the authors have described one useful and accurate method for each procedure. We note that they suggest placing the thumb over the opening of the Sahli hæmoglobin tube and inverting it; this is a method often followed in practice but it is one that must decrease the accuracy of the estimation.

In the chapter on the causes of anæmia a very reasonable classification is given. The writers have of course departed from the old classification of primary and secondary anæmias and have adopted one dependent on ætiology; their four main groups are, dys hæmopoietic anæmias, hæmolytic, hæmorrhagic, and anæmias of unknown cause. They have not, however, given any table of classification—perhaps they think this would be a little premature in our present state of knowledge—nor do they follow this classification in their subsequent division of the subject into chapters.

Blood diseases themselves are considered in twelve chapters which form the main bulk of the book. The writers are fully conscious, even if they have not referred to each worker individually, of all the recent work on this extensive subject and there are numerous references to papers published in 1935. These chapters will be found equally valuable to the student who wishes to read up the subject from 'a to z' and to the physician who wishes to look up any particular point that has arisen in his practice, as the chapter, section and paragraph headings are well conceived and there is a useful subject index.

At this point we must come to our quarrel with this otherwise most excellent book. We do not understand why the chapter 'Infection and Infectious Diseases' ever found its way into the book. To give concise details of some of the characteristic blood changes that occur in various infectious diseases was sound enough and this is apparently what the writers started out to do; they were successful up to a point, but then for some unaccountable reason they seemed to have been lured into giving short accounts, containing little reference to the blood picture, of a number of tropical diseases, about which they obviously know very little. In the three pages devoted to leishmaniasis they have managed to cram an incredible number of naïve, irrelevant and misleading statements. One is told that 'the organism resembles the degenerating forms of certain trypanosomes', that it has two nuclei of different size and that the larger may be bi-lobed, that kala-azar occurs in nearly all parts of India, that when doing a spleen or liver puncture one's object should be to draw 'lymph' and to avoid blood, a Portian warning that would shake the nerve of any modern Shylock, even if he did happen to know where he could expect to find 'lymph' in a liver or a spleen.

There is one other chapter that we should mention, that on blood grouping and blood transfusion technique. This is short, but gives the essentials, and will be very useful to the practitioner, as hitherto he has had to refer to one of the larger books on laboratory technique for the former and to a book on surgical technique for the latter.

At the end of each chapter is a short list of references that the reader will find very useful indeed, and there are some excellent coloured plates. The whole book forms an extremely valuable contribution to the subject of blood diseases and will be welcomed alike by the clinician, the laboratory worker, and the medical investigator. The format of the book is of the high class that we have been led to expect from this well-known firm of medical publishers. It is a book that we can thoroughly recommend to medical readers of every class.

L. E. N.

A TREATISE ON HYGIENE AND PUBLIC HEALTH—WITH SPECIAL REFERENCE TO THE TROPICS.—

By B. N. Ghosh, F.R.F.P. & S. (Glas.). Revised and largely rewritten with the assistance of A. D. Stewart, C.I.E., M.B., F.R.C.S.E., D.P.H., D.T.M. & H., Lieut.-Col., I.M.S. Eighth Edition. 1935. Scientific Publishing Company, Calcutta, India. Pp. xv plus 660, with 163 illustrations. Price, Rs. 7-8

The eighth edition of the *Treatise on Hygiene and Public Health* by Birendra Nath Ghosh appears within 24 years of the first publication of the work under the joint authorship of Ghosh and Das. The author has been fortunate in getting the valuable help of Colonel A. D. Stewart in the general revision of this edition and the help of Colonel Covell, Dr. E. Muir, Dr. Keshava Pai and Dr. K. V. Krishnan in revising special sections of the book. The book is a store of information on public health subjects and is alive to the special needs of the students in the tropics. Treatment of the subjects is on the whole lucid and the treatise has kept abreast of the latest work. The book is deservedly popular with students and public health workers and the desire to see it free of blemishes prompts the reviewer to draw attention to the following which appeared to him to be either inaccurate or inexplicit, when reading through certain sections of the book.

(1) In the description of the chemical and bacteriological tests of water (are these not rather out of place in a book of this type?) on page 61, the definition of typical *B. coli* should be amplified; on the same page under total colony count the statement 'this gives the total number of bacteria of all kinds in the sample' is incorrect.

Under *B. coli* count on page 62 in the instruction on the seeding of water, 10 c.cm. quantities are skipped over and too many 20 c.cms. find place; on the same page we are told that the varieties of *B. coli* are separated into four groups by their reaction on saccharose and dulcitol, the particular classification referred to should have been stated.

The term faecal bacilli frequently crops up but it is not used in the same sense as is done in present-day bacteriology.

(2) The seeds of mustard grown in Bengal from which mustard oil is pressed out are—

Brassica Napus (var. *Dichotoma*)—(Indian rape),

Brassica Campestris—(Indian Colza), and

Brassica Juncea (not *Junce*)—(Rai),

and there exist many more species which are not grown in this province.

The statement on page 227 that there are three varieties of mustard seeds should therefore be corrected and modified. We miss linseed oil among the common adulterants of mustard oil.

In the section on preventable diseases, under plague, some of the characters of *Pasteurella pestis* described appear to be redundant; on page 477 'it has remarkable power against cold' should be 'remarkable power of resisting cold'.

Why a partially blocked plague-infected flea is more dangerous than a completely blocked one should be more clearly stated.

Under cholera, the reference to Tomb and Maitra's work on cholera on page 495 might be made clearer, and the statement on page 494 that atmospheric moisture may convey the virus is rather vague. Is it meant that the vibrios can be carried over during the process of vaporization of water?

More could have been written on the epidemiology of cerebrospinal fever in view of the recurring epidemics in India, and finally epidemic dropsy and beri-beri should have been treated separately.

A. K. S.

LABORATORY MANUAL OF THE DEPARTMENT OF BACTERIOLOGY AND IMMUNOLOGY, PEIPING UNION MEDICAL COLLEGE. Prepared under the direction of C. E. Lim. Second Edition. 1935. Published by the Division of Bacteriology, Peiping Union Medical College, Peiping, China. (Printed at the Kwank Yuan Press.) Pp. 190. Price, \$1.50

As an outgrowth of the worksheets of a large teaching and research institution, this little manual will prove of great interest and value as a guide to all laboratory workers for whom it provides a useful compendium of laboratory methods that have been proved accurate and convenient.

The chapter on laboratory animals especially is excellent and contains much useful information. All details for breeding, handling, transportation, experimentation and disposing of animals are given in brief. These details together with the table giving the hematology of animals commonly employed in experimental bacteriology will be frequently referred to by many laboratory workers.

Another feature of the book is that, although references are given at the end of each chapter, a special chapter is devoted to providing an excellent selection of reading references. All the most recent and standard works are included in the list which should prove a valuable guide to students for whom it is primarily intended.

Sections on staining methods, and on pathogenic fungi together with the instructions for the autopsies of animals and the brief description of a few biochemical tests have added to the scope of the second edition.

The manual is small, compact and well printed and should find a place beside *Stitt's Manual of Bacteriology* in all clinical laboratories.

A J H DE M

RADIOLOGICAL ATLAS OF CHRONIC RHEUMATIC ARTHRITIS (THE HAND).—By S. Gilbert Scott, M.R.C.S., L.R.C.P., D.M.R. & E. (Camb.). 1935. Oxford University Press, London. (Humphroy Milford.) Pp. xiv plus 76, with 30 plates. Price, 25s.

The hand has been called 'the visiting card of the rheumatic patient'. In this excellent publication Dr. Scott has in his own inimitable manner set forth the mere important radiological features met with in arthritic conditions, showing the bony changes seen in the hand and very lucidly explaining the reasons therefor in the underlying pathology. This is certainly one of the clearest expositions we have seen of the distinctions between rheumatoid or atrophic arthritis, hypertrophic or osteo-arthritis, chronic infective arthritis, and gout. The book will be found invaluable by both clinicians and radiologists. The plates illustrating it are admirable.

G G

DISEASES OF THE THYROID GLAND.—By Arthur E. Hertzler, M.D. With a Chapter on Hospital Management of Goitre Patients. By V. E. Chesky, M.D. Third Edition, Entirely Rewritten. 1935. The C. V. Mosby Company, St. Louis. Pp. 348. Illustrated. Price, \$7.50

The part played by the endocrine glands is becoming more important every day as fresh problems arise, and the third edition of this present interesting volume will be welcomed by physiologists and clinicians alike. The vast experience on the subject of Professor Hertzler is embodied in the pages of this treatise, and his study has brought convincing evidence before the medical profession that the activity of the interstitial cells is associated with a definite clinical type of thyroid intoxication.

The book has been divided into a number of chapters dealing with the anatomy and physiology of the gland, effects of derangement of the function of the gland, the varieties of goitres developed both during childhood and adolescence with their recent nomenclature and

classification, malignant growths of the gland, and the morbid anatomy of such growths. The description of goitres in unusual places has considerably added to the importance of the book. The concluding chapters include the hospital management of goitrous patients, their treatment both medical and surgical and the various complications arising during such treatment, all discussed from a practical point of view.

Lastly the author has described operative technique relating to the gland, the choice of a suitable anæsthetic during such operations, the details of which are of particular value.

The book is beautifully printed and lavishly illustrated with excellent drawings; for the most part they are made up of clinical photographs which speak of the author's personal experience and impressions on the subject. The book though fairly compact contains a wealth of information and will be of equal interest both to the practising physician and the specialist.

MEDICINE FOR NURSES.—By W. Gordon Sears, M.D. (Lond.), M.R.C.P. (Lond.). 1935. Edward Arnold and Company, London. Pp. vii plus 412. Illustrated. Price, 8s. 6d.

This volume is a comprehensive book for nurses, based on a course of medical lectures given to those who are in training on the syllabus of the General Nursing Council for England and Wales; to such it will prove a most useful book.

However, it lacks sufficient information on tropical diseases to be of great use to nurses training in India, but in other respects it will be an interesting addition to the nurses' library. Useful illustrations appear and the book is nicely printed on good paper.

The chapter on infectious diseases is very comprehensive, and that on deficiency diseases equally so and will help the nurse to a clearer understanding of this subject.

M. E. A.

Abstracts from Reports

REPORT OF THE EUROPEAN MENTAL HOSPITAL AT RANCHI FOR THE YEAR 1931 BY MAJOR MOORE TAYLOR, M.D., D.P.H., I.M.S., MEDICAL SUPERINTENDENT

The number of patients resident in the hospital at the beginning of the year was 203 (101 males and 102 females) against 203 (99 males and 104 females) in the preceding year, while the maximum number resident on any one night was 215 (105 males and 110 females) against 212 (107 males and 105 females) in the previous year. The total admissions during the year under report was 72 (33 males and 39 females) against 54 (37 males and 17 females) in the previous year. Of these, 29 were re-admissions (15 males and 14 females) against 26 (15 males and 11 females) in the previous year.

The general bodily health of the patients has been good, and there was no epidemic of any kind throughout the year.

The daily average of sick treated in hospital during the year under report was 381 (150 males and 231 females) against 408 (164 males and 244 females) in the preceding year.

No form of seclusion or restraint has been adopted during the year under report, nor has it been necessary to withdraw parole from any patient.

To-day in the United Kingdom and in the United States of America, there are twice as many hospital cases of dementia præcox (schizophrenic reaction types) than tuberculosis, and, were statistics available, it would, I am confident, be proved that a similar state of affairs exists in India. In this hospital no less than sixty per cent of the patients are of this type. The

ætiology of this disease is still unsettled, its pathology is unknown, and its clinical limits are in dispute, yet it is a more serious problem than either tuberculosis or carcinoma.

During the last two decades we have seen enormous advances in every other branch of medicine, but the psychiatrist struggles with his most difficult burden of advance alone. The anatomist, the physiologist, the bacteriologist, the virus worker, and the biochemist have, so far, done nothing material to clear the path for his progress. Psycho-analysis has undoubtedly thrown light on some of the symptomatic mechanisms, but psycho-analysts themselves doubt its efficiency as a therapeutic procedure during the psychoses. Far be it from me to condemn psycho-analysis, but before it is undertaken it must be borne in mind that the prognosis will depend on (1) whether the difficulties can be brought into consciousness, and (2) whether they can be dealt with successfully by the patient, if they are so brought. It is difficult to believe that the mere bringing of them into consciousness is enough, and it not infrequently happens that, when an unconscious trouble is made conscious, it is found to be of a kind with which the patient cannot deal, and to which he cannot reconcile himself. The patient's condition may be made much worse, not only for the time being, but permanently. Much has been written concerning psycho-analysis but there have been comparatively few impartial surveys of the subject. The present consensus of opinion, however, would appear to be that in psycho-analysis there are many weaknesses. Analysis of the unconscious is, at any rate, an extremely difficult and delicate procedure, analogous to a major surgical operation, and should only be attempted with a sense of grave responsibility.

One might quote the sound advice of that very eminent psychiatrist, the late Sir Maurice Craig, C.B.E., M.D. (Cam.), F.R.C.P. (Lond.), for many years consulting physician in Psychological Medicine at Guy's Hospital, London, who said 'the physician whose attitude of mind leads him to prefer psychical to physical ætiology should beware of overlooking a collection of pus in his preoccupied concern with the patient's mental confusion and hallucinations. Delighted as he may legitimately be in tracing an anxiety neurosis to a forgotten incident of childhood, in replacing a maladaptation to the facts of life by a wiser and saner mental outlook, hours of misplaced psycho-analytic enthusiasm may be saved by a urinary test or a glance at the optic discs'.

One is confronted with many difficulties in mental diseases—the factors may be in consciousness although the patient has not correlated them with the fact that he is ill, while in others the difficulty may be one which is unconscious. For many patients there is an apparent advantage in illness, and the type of persons who take refuge in illness, every time that life becomes exceptionally troublesome, is even found in mental hospitals, and occasions do arise when patients have literally to be pushed out.

In the causation of mental disease, the old controversy on heredity versus environment continues. Both are in some measure factors, but in view of the modern connotation of the term mental disease and mental deficiency it is felt that environment plays a greater rôle than is generally realized in certified cases.

In discharges and re-admissions two problems are involved, the eugenic and economic.

Jenning's researches dispel the idea that mental defect can be eliminated by preventing the propagation of mental defectives. He claims that the great number of defective genes that give rise to abnormalities are present also in normal individuals. Other eminent investigators also express views which give no aid to the propaganda for bettering the human race by sterilizing our patient. At a time when American literature is so favourable to sterilization of selected types, it is a pleasant diversion to find some who sincerely see nothing to be gained by it. At the same time, however, the responsibility of sending a patient forward

to the committee of visitors with a recommendation for discharge is no light one. Experience proves that the discharged patient is frequently a burden and a nuisance to relatives and friends. To a once successful and prosperous individual, this, together with a lack of suitable employment, and the dreary round of job-hunting, is frequently the cause of re-admission. The patient, reduced to shabbiness and shaken in morale, quickly drifts into irritability, panics, depressed states and even delusions of persecution, and the psychiatrist has the discouraging experience of seeing his patient returning sometimes worse than ever. I am convinced that, in a large number of patients, the main underlying cause of their condition is a difficulty to find access to a regular job and economic independence, and the inability to hold any but the poorest jobs. Disturbed attitudes, loss of health and morale, due to the deprivations caused by unemployment, undoubtedly lead to psychological undermining. This has been vividly witnessed among those out of work for both a short and long period.

The economic factor is one which affects this hospital more than any other in India. Patients are brought from long distances, and it has frequently happened that the expenditure in sending them home and having them returned to hospital has been more than three or four times the amount which it would have cost to maintain them for the short periods they were able to remain out of hospital. This re-admission rate is an extremely important one, and in order to focus attention on the real state of psychological medicine, I am of the opinion that it would be better if psychiatrists were to be a little more conservative in the use of the word 'recovery'. Instead, one might suggest that the term 'good result' might be utilized for patients who remain out of hospital and require no treatment for over a year, 'very good result' for patients who remain out for over two years, an 'excellent result' for over three and under five years. The term 'recovery' might be reserved for those not requiring hospital treatment for over five years.

The reports of practically all mental hospitals reveal the fact that many patients have been sufferers from mental disease for many years before any appropriate or skilled treatment has been administered. Approximately eighty per cent of patients, when admitted to hospital, could be classified as 'chronic' and this state of affairs will continue, so long as our medical men receive inadequate instruction in psychiatry.

In the better medical schools, psychiatry is regarded seriously, though not so much time is given to teaching as some of us think necessary, but in some schools in India no instruction is given in psychiatry whatsoever. No individual should be granted a licence to practise medicine until he at least knows the rudiments of psychiatry and has gained a working knowledge of the more common forms of mental disorder, and it should be the concern of all teaching bodies that young practitioners should be taught to develop a sound understanding attitude towards the psychological, educational, and social aspects of medicine. The young doctors must, above all, be taught that the majority of cases of insanity which receive timely and appropriate treatment are curable, and to feel that they have failed in their duty when they merely call in the specialist when it is too late, and then, under his guidance, sign a certificate of insanity.

In the year under review no startling facts have been uncovered in the treatment of mental diseases. There are no tricks in psychiatry, and the casual observer visiting a mental hospital may, at first sight, jump to the erroneous conclusion that nothing is being done for the insane. Even medical practitioners will frequently ask what special form of treatment is given, and will be amazed to find that, with the exception of a few suitable patients who are undergoing treatment with special drugs, medicinal treatment is limited to the occasional use of sedatives, hypnotics and purgatives.

Physical ailments frequently accompany mental disease, and teeth, eyes and feet usually show lack of care, as well as minor digestive troubles. There is on the staff of this hospital a qualified visiting dentist who takes over the care of the teeth immediately the patient is admitted, and the minor physical ailments, which are sometimes cherished by the patient, are appropriately dealt with. It might be asked them 'what is done for the mental patient'?

The sheet anchors in treatment continue to be good nursing, dieting, the careful use of drugs, hydrotherapy, psychotherapy, and among these occupational and social therapy take the prominent place. The value in this line of treatment lies in the fact that the patient is made to realize that there are still some things which he can do successfully, and although he has failed outside, it is important for him to recognize that he can succeed under hospital conditions. An attempt is also made to restore the patient's self-respect, and efforts are made to abolish the imaginary stigma of a psychosis. The patient is approached upon his own intellectual perceptive, emotional and volitional level. This may appear to be a dogmatic formulation, but both the psychiatrist and the therapist will readily recall many cases of failure due to deficient, excessive, or distorted function of these elements of the personality. It is always necessary not only to explain the methods of the proposed therapeutic project but also the reason for it. Emphasis is laid on its social co-operative nature and significance in developing the patient's capacity. Provision is also made for progression and graduation, and formal recognition given to the patient who has advanced to a higher grade.

Only the infirm and physically unfit are excused attendance at the occupational department. Over 80 per cent of the patients in this hospital are employed in work which is interesting to them. The selection of work is carefully made by the Medical Superintendent in consultation with the occupational therapists, a prescription is made out and progress carefully recorded, and changes made where necessary, otherwise there is apt to be irritation, friction, disorder, boredom, and introspection.

The patient will, if capable to that extent, receive training in manual and industrial arts, the preparation and serving of foods, raffia work, cane-work, basket-making, chair-making, rug-weaving, carpentry, embroidery, the use of the fret-saw, weaving, sewing, crocheting, knitting, and even more intricate work, which may have little actual industrial value in later making him or her self-supporting in the community, but will at least provide satisfaction in terms of creative value, and fill the thoughts to the exclusion of anything less desirable.

The patient is quickly impressed by the attitude of tolerance and understanding in which he is approached by the medical and nursing staff of the hospital. He sees that an attempt is being made to create a closer relationship through genuine, personal, kindly and understanding interest. The successful psychiatrist and the mental nurse must first have learnt 'the art of being human', and to make the patient feel at ease and comfortable, and not to attempt to exact at first too much from the autistic personality of the patient. It is necessary to realize the essential slowness of the readjusting process. Intolerance and impatience must have no place in the treatment, and it has always to be remembered that the most precious and coveted possession of the patient is his individual personality, and he must be made to feel that his rights are guaranteed.

Let me here pay a tribute to the staff of this hospital. Their work is of a very high standard indeed. The deputy superintendent has been on the staff for over ten years, the senior house physician over eleven years, the junior house physician over five years while the matron has over sixteen years, and no nursing sister has less than three years' service, the periods varying from three to eleven years. The medical staff, the nursing staff, and the occupational therapists are

required to attend the clinical meetings, for it goes without saying that the nurse or the therapist, who does not know one disease entity from another, can be of little value, and probably do much harm.

There is a weekly dance at which the hospital band plays and, in addition, there is a cinema weekly and sometimes bi-weekly.

The Roman Catholic and the Church of England chaplains conduct services in the respective chapels every Sunday.

No hard and fast rules are laid down regarding the social therapy, because the particulars depend on the individuals themselves. The games, dancing, participating in sports, etc., are used as a means of socializing the patients, and widening interests in all possible directions.

It is recognized in all modern mental hospitals that occupational and social therapy are the most useful agents we possess in promoting improvement and recovery, and in this hospital this department is being further developed.

Selected patients are now permitted to arrange their own bridge-parties and, during Christmas of last year, a large number of patients organized and formed themselves into a carol singing party and made the round of the residences in the vicinity of the hospital. They collected a sum of Rs. 30 which they later expended on a picnic for themselves and some of their friends.

During the year the patients have also given many excellent concerts, which have been enjoyed by many members of the public. A special tribute is due to Sister Mason and Mr. Bose, the physical culturist, who organize these concerts. To Captain Mayes, the house steward, who continues to act voluntarily as bandmaster, I also extend grateful thanks.

During the year under review, 42 patients (24 males and 18 females) were discharged as recovered or improved. All underwent treatment in the occupational and social therapy department. The favourite occupations for the males appeared to be carpentry and weaving, while the female patients elected needle work, crochet and cookery. Knitting socks and stockings by machine, and Italian embroidery are new occupations which have been introduced in the female section during the year.

The hospital has now a first class gymnasium which has been fitted up with parallel bars, bridge ladders, Roman rings, rowing apparatus, etc., and physical culture has proved very popular with a large number of the patients. On Founder's Day an acrobatic display and a torch-light tattoo were held on the sports ground, and many of the patients exhibited great skill.

During the summer months, batches of patients were taken to the lake for swimming and rowing, and in seasonable weather the usual weekly picnic parties were organized, and despatched to the various beauty spots within a twelve-mile radius of the hospital.

Two fancy dress dances were organized for the patients, one during the Puja holidays and one during the Christmas vacation. These were thoroughly enjoyed and over 100 patients appeared in really excellent costumes, all of which were made in the occupational department. A combined concert by the staff and patients was given at Ranchi and the proceeds of over Rs. 200 were donated to the Viceroy's Earthquake Relief Fund.

One patient, who showed no response to any treatment, is now being given lessons on the pianoforte, in which she is taking a very keen interest.

On the whole, the co-operation of the patients has been excellent, but in order to stimulate interest in work, and to check indolence and truancy it was necessary in 27 cases to introduce a system of food tickets. Lunch was only served to those of the 27 who had earned a ticket. The main rationale of this procedure was, of course, neither punitive nor coercive, but essentially co-operative. In 26 cases, rapid improvement occurred and there have been no relapses to

indolence. In only one female patient there was no improvement. No patient is on this system at present.

Every day about 60 per cent of the patients participate in outdoor games. Seven cricket matches were played with outside teams, and of the total the hospital won five. Inter-section football and hockey matches were frequently played. The hockey shield this year was won by the South Section and the football shield by the North Section. Cycling is still very popular and there are at present 15 cycles and one tricycle in the hospital, reserved solely for the use of the patients, but this number is inadequate to meet all demands, and they are given out in rotation. Tennis, badminton, croquet, and basket-ball are indulged in every day.

Special treatment.—In seven cases of maniacal excitement treatment by hydrotherapy was used with success. In three cases prolonged narcosis by somnifen injection was tried, but all three patients failed to respond to this treatment. In eight cases where somnifen was used orally slight improvement occurred.

Sulfosin alone, and also combined with solganol, has been tried in many cases of schizophrenia and manic-depressive reaction types, but without success. One case of manic-depressive insanity was discharged recovered, but it is doubtful whether any claim can be put forward for this special form of treatment. It may have been a natural remission. Success has been claimed for this method of treatment in some institutions, but in view of the negative results achieved in this hospital, and the extremely painful nature of the treatment, we feel compelled to abandon its further use.

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1933. VOLUME II ON THE HEALTH OF THE ARMY IN INDIA

Cerebro-spinal meningitis.—Hitherto only sporadic cases have occurred among British troops at rare and irregular intervals. Among Indian troops cases have been more common, particularly in certain recruiting battalions. The disease as it occurs in India is of a severe and fulminating type, and death frequently ensues within 48 hours of the onset of symptoms. The mortality rate is extremely high, averaging 70 per cent over five years. As serum is administered (intrathecally and if necessary intravenously and intramuscularly) in all cases there is little evidence that this form of treatment has any effect on the course of the disease.

The disease has of recent months shown a marked increase among the civil population and the situation presents several disquieting features.

Cysticercosis.—Interest in this condition, as it affects India, has been revived in consequence of recent and important work on the subject.

Prophylactic measures advised were of a general nature, because the exact mode of infection is not yet known—although carrier infection is suspected. At present there is no evidence to show that human cysticercosis is the result of auto-infection.

Dengue.—As heretofore, the majority of the cases of dengue have occurred in the personnel of garrisons in seaport towns. Owing to the proximity of the barracks to areas occupied by the civil population, the problem of eliminating the vector of the disease is a very difficult one.

Sandfly fever.—The figures for sandfly fever have remained at a very constant level for the last three years. The majority of cases continue to occur in Northern India, and particularly in certain stations on the North-West Frontier.

Sandfly fever has been the subject of special investigation during the year.

The entomological aspect of the problem has been studied in Landikotal, where the investigations were directed by a specially trained worker detailed by the Indian Research Fund Association.

As far as they went, the results obtained were satisfactory. The exact local conditions required for sandfly breeding were defined, and once this had been

done no difficulty was experienced in locating innumerable breeding places. So widespread are these conditions that the problem of control appears, under Indian conditions, to be practically insoluble. In compact and well administered areas such as Landikotal itself, something might be accomplished: in straggling cantonments such as Peshawar the problem is a hopeless one. Work is nevertheless being carried out to determine the best method of treating breeding areas so that this knowledge may be available should special circumstances arise calling for its application.

It was mentioned in last year's report that it seemed possible that infection was being acquired (as far as Landikotal is concerned) through men being bitten while on duty at night in the perimeter defences. Control observations were made during 1933 on a group of men who at no time were on night duty on the perimeter. The incidence in these men showed no appreciable difference from that in the remainder of the garrison, from which it would appear that infection is being acquired in the barrack rooms as well as elsewhere. The complaint made by the men that they are bitten more severely while on the perimeter is probably due to the fact that, being awake, they notice the bites to a greater extent.

The investigation of the aetiology of the disease, which has been going on at Peshawar, has produced interesting results. In 1932 certain observations were made which suggested that the causal organism in at least a proportion of cases (for it was thought that clinical variations in type could be detected) was a leptospira.

By carrying out a large series of blood cultures (some 500) under ideal and carefully controlled conditions, this theory has been definitely disproved, and it can confidently be stated that sandfly fever of the Indian Frontier is not leptospiral in origin.

On the other hand, experiments which are not yet in a final state leave little doubt that a filter-passing virus is responsible, and attempts are being made to obtain this virus in a fixed form, in the hope that this may prove a stepping-stone to the production of some form of immunizing agent.

Fever of the typhus group.—An increase in the number of cases of this condition which have been diagnosed is probably to be attributed to a more widespread knowledge of the subject.

While the disease is more common in certain localities than in others it is nevertheless widespread throughout the country.

No definite progress has been made as regards the detection of the vector of this disease in India, but opinion is gaining weight that the tick is by no means the only arthropod involved.

Diphtheria.—Diphtheria is a disease in which the information given by the laboratory can on occasion be very confusing. In the straightforward case with clinical signs no difficulty exists. Treatment is inaugurated at once on the strength of the clinical data and the laboratory affords confirmation of the correctness of the procedure. In cases which clinically are suggestive, but doubtful, the result of the examination of a swab is invaluable. But in those cases of sore throat where no suggestion of diphtheria exists, but where a precautionary swab is taken, the outcome is often dire confusion. Experience has shown that innocuous diphtheroids which are morphologically indistinguishable from *Corynebacterium diphtheriae* are of relatively common occurrence. Where such are found present in the swab, few clinicians will accept the responsibility of treating the case other than as one of diphtheria until negative information is afforded by biochemical or biological tests. This involves swabbing and segregation of contacts, and frequently leads to numbers of men being unnecessarily off duty.

To minimize this as much as possible, special investigations have been made into the technique of isolating and testing the virulence of the organism, and a method has been devised which reduces considerably the interval of time necessary to give a definite result.

Dysentery, diarrhoea, colitis and amebic hepatitis.—In the last ten years there has been an upward trend in the admission ratio for these diseases. This has been attributed to the greater interest taken in the subject and to the fact that the necessity for reporting sick in all cases of the kind is constantly being impressed on all ranks.

A study of the different types of infection in bacillary dysentery throws an interesting light on the epidemiology of the disease. Some fifteen to twenty types of dysentery bacilli, of which ten are of comparatively common occurrence, can now be differentiated. Occasionally there may be a group or series of cases which is caused by the same type of organism, and is therefore referable to a common source. More frequently, however, this is not the case, and if an analysis be made of the types of bacilli in all cases occurring in a regiment in one season, it will be found that great diversity exists, and that few if any of the cases are aetiologicaly related to each other. In other words, infection is not due to case to case spread within the unit, so much as to a constant bombardment from the massive and varied reservoir which exists among the civil population.

Within the confines of his own lines the soldier can be, and in most instances and to a large measure is, protected against infection. But it is neither practicable nor desirable that he should be constantly confined to barracks, and as soon as he moves afield the chance of safeguarding him from infection becomes remote, despite such measures as are taken regarding restaurants and other similar establishments. The diversity of organisms which are isolated is clear evidence of the fact that he derives his infection from such widespread sources.

In the absence of protective inoculation, it would seem that the reduction of diseases of this group can only be affected by raising the standard of sanitation among the civil population. In the cantonments much can be, and is being, done; but where there exist adjoining municipalities, or worse still villages in which sanitary control is practically non-existent, the problem is one which bristles with difficulties. Any improvement which may ensue will be of very slow development.

Tropical abscess of liver and hepatitis.—In all, 59 cases of liver abscess and hepatitis were admitted of which 36 were considered to be amebic in origin. This is a considerable drop from previous years. Five of the 36 cases were diagnosed as amebic abscess, but only 2 were treated surgically. There were no deaths nor invalids. One case relapsed twice.

Enteric fevers.—The variation in the number of cases occurring amongst British troops in three years is trifling.

The cases were sporadic in origin with the exception of an outbreak of 16 cases of typhoid fever in a detached company of infantry at Muzafferpur and an outbreak of 9 cases of paratyphoid A in Allahabad. The outbreak of typhoid fever was one of great severity, there being four deaths (*i.e.*, a case mortality of 25 per cent) and seven other cases whose condition gave rise to grave anxiety. The type of cases was in fact, in no way different in severity from that described in preinoculation days; and it is significant to note that all these men were 'protected', *i.e.*, inoculated with two doses of T. A. B. vaccine within a period of 18 months. This gives further support to the observation made in a previous report, that inoculation, although it definitely appears to lower susceptibility to infection, has little if any action in mitigating the severity of an attack when this is established. The source of infection was not traced, but there is reason to believe that milk which found its way into the lines from an unauthorized source was responsible. All the patients were in the habit of drinking milk as a beverage.

The outbreak of paratyphoid A was mild. It was traced to a carrier—a coffee-shop employee—who had been working in the same establishment for three years,

and who therefore had presumably acquired his infection recently.

The position as regards diagnosis remains unchanged. Early blood culture is without question the most satisfactory method. Faeces and urine culture lend little assistance, and the agglutination test, while on occasion it may be of positive value, is of no negative significance. For use in this test concentrated suspensions of organisms are being issued with satisfactory results. Owing to the certainty with which batches of suspension can be prepared of a uniform standard, the 'standard agglutinin unit' is being abandoned, and results will be expressed in terms of the denominator of the dilution in which standard agglutination occurs, an interpolation table being used where necessary.

T. O. suspensions continue to be used as a routine in these tests, and certain laboratories have experimented with A. O. and B. O. No striking results have been obtained, and the opinion is gaining weight that this test adds little to the results obtained by the older methods of diagnosis.

In view of the conclusions reached at the R. A. M. College regarding the Rawlings strain of *Bact. typhosum* which is used in the manufacture of T. A. B. vaccine, this question as far as it concerns India has been given close attention. T. A. B. vaccine for use in India is manufactured by the Central Research Institute, Kasauli. Here, as elsewhere, the Rawlings strain has been used, but from time to time this strain has been subjected to animal passage and as a result has maintained a 'smooth' character. In addition to strain Rawlings, however, it has for some years been the practice to incorporate equal parts of a recently isolated and definitely smooth strain of *Bact. typhosum* in the vaccine. It would therefore appear that the Central Research Institute vaccine has been manufactured throughout from 'smooth' strains of *Bact. typhosum*.

While this subject was under review, some very striking figures were compiled in regard to the incidence of 'proved' typhoid fever in the first and in subsequent years of service in India. The proportionate admission ratio, case mortality and death ratio among men of over 1 year's service and under 1 year's service are as follows:—

	Over 1 year	Under 1 year
Admission ratio ..	1	4
Case mortality ..	1	2.1
Death ratio ..	1	8.6

There are various causes which may contribute to this state of affairs. Assuming exposure to infection to be more or less universal and inevitable, susceptible individuals who have little or no resistance even after inoculation are likely to be picked out early in their Indian service. Naturally-developed immunity will be higher the longer the man serves in the country, and in the same way repeated inoculation may have a cumulative action. Also the old soldier becomes more experienced in looking after himself. It will be of great interest to observe the effect which the use of the R. A. M. College vaccine has on the incidence of typhoid fever during the first year of service.

The policy of examining menials for the carrier condition has been maintained. In all 11,560 menials were examined, a total of 39,657 stools being plated. This resulted in the detection of 3 carriers of *Bact. typhosum*, 2 of *Bact. paratyphosum A*, and 1 of *Bact. paratyphosum B*. At first sight this seems a poor return for the labour and time expended. On the other hand, the work has fulfilled its purpose as there have been no outbreaks traceable to the enlistment of a carrier.

Malaria.—[Under this heading there is a full and interesting discussion on the reasons for the differences in the years 1933, 1932 and 1924. These years have

been chosen for comparison because 1932 was the best and 1924 the worst malaria years for the British Army in India. This discussion does not lend itself to abstraction and we are unable to give it in full for want of space, but it is a valuable contribution to the epidemiology of malaria in India and should be read in the original. We give, however, the concluding remarks on this section which gives a summary of the position in 1933.]

In Northern Command the relapse rate has fallen from 50 to 40 admissions per 1,000 of strength. This fall would have been more marked if the command had enjoyed peace conditions. Field service operations at the worst part of the year entail heavy and repeated infections and, in some cases, inadequate treatment.

Approximately a quarter of a million mosquitoes were trapped in the Peshawar barracks. Trapping was also tried out with success at Bannu. The value of this measure is enhanced when it is employed in barracks adjacent to breeding grounds which cannot be effectively controlled.

At Kohat the incidence of the disease shows a distinct tendency to diminish and the mosquito-proofing of the McQueen lines has probably played an important part in this most desirable result.

A comparatively large number of fresh infections were reported from the hill station of Razmak. No doubt the bulk of these represent infections of troops on detached duty at Bannu and Dera Ismail Khan.

At Lahore senior Boy Scouts were trained in anti-malaria measures, and did good work in the sadar bazar area.

In Eastern Command the improvement in the malaria statistics would have been remarkable had it not been for adverse conditions in Delhi. The ratios per 1,000 for this station are disturbing; they show a deterioration of the situation thus—

1929	114.3
1930	191.4
1931	200.4
1932	198.3
1933	309.4

The situation in Western Command also gives rise to anxiety. Here the per mille figures were:—

1929	130.9
1930	92.8
1931	140.8
1932	131.1
1933	204.0

Temporarily, at least, this command has lost the reputation for salubrity which it formerly enjoyed.

In Southern Command, Jubbulpore and Mhow—formerly the two worst stations in the command—were placed 7th and 3rd respectively in the incidence table. Trained antimalaria officers have been in charge of these two stations for some years, and it would seem that their labours are at last bearing fruit.

The problem of malaria in India, in all its many facets, is of never-failing interest. This interest, to sanitarians and clinicians alike, was fully maintained during the year under review. However, in this field of medical activity caution is a desirable quality; and it may be well to allow Mr. Jorrocks to write the epitaph of 1933, thus:—'Far be it from me to say that you will be much wiser from anything you have heard, for the old stager will find nothing but what he knew before, while all that can be taught the beginner is not to be too sanguinary in his expectations'.

Plague.—This tropical scourge, like cholera, makes its appearance in the pages of Indian sanitary reports with a fair degree of regularity; but nowadays, in British health reports, it is an uncommon subject.

A severe epidemic of the disease occurred in the Bombay Presidency, and notably in the civil-municipal areas, Poona. These areas surround, are contiguous to, and are even thrust well within, the cantonment area.

Early in August a very virulent and severe outbreak occurred in the village of Ghorpuri. This village was

not under military control, and its position as regards the troops' quarters was most dangerous. The villagers refused to co-operate in the anti-plague measures advised. On the 24th of August dead plague-infected rats were found inside the cantonment boundary. By the middle of September all troops had been inoculated against infection. Regimental and cantonment rat extermination squads were trained and set to work on an intensive anti-rodent campaign. Trapping was not found to be nearly as successful as baiting: 'Common sense' rat bait and barium carbonate were used.

Kirkee cantonment, near Poona, also became infected, but less severely. Gradually, rodent infection spread: dead infected rats and squirrels were found all over Poona cantonment. The epidemic began in the city of Poona in January 1933. It smouldered on through the hot weather, and flared to its height in August, September and October. Before the plague exodus took place, the population numbered 160,000. A conservative estimate, up to the end of November, puts the number of attacks at 1,400, with 984 deaths.

In the cantonment, between 30th September and 28th November, 1933, only 14 cases occurred, and no British personnel contracted the infection.

There is no doubt that, but for the energy and enthusiasm displayed by the medical and executive officers in charge of this alarming epidemic, the results would have been very different, and probably very disastrous.

Rabies and prophylactic anti-rabic inoculation.—No comments on this subject have been made for some years.

Prophylactic anti-rabic inoculation has now been almost completely decentralized from Pasteur institutes. Military anti-rabic centres exist in all the larger stations, except a few in which convenient civil centres are established.

Carbolized vaccine is obtained by military centres from the nearest Pasteur institutes. The system of dosage has not been finally standardized, and military centres conform to the practice of the institutes from which their vaccine is obtained. For statistical purposes comprehensive details are obtained in every case and supplied to the parent institute.

This system has proved very satisfactory, and in every way preferable to the old system of despatching individuals, often under the most trying weather conditions, to distant Pasteur institutes. Command and District Laboratories now undertake the examination of the brains of suspected rabid dogs.

THIRTY-SECOND ANNUAL REPORT OF THE BUREAU OF SCIENCE, PHILIPPINE ISLANDS, FOR THE YEAR ENDING 31ST DECEMBER, 1933. BY ARTHUR F. FISCHER, ACTING DIRECTOR

THE work of the Bureau of Science for the public covers a wide field and directly or indirectly touches almost every phase of human activity in the Philippines.

The health of the public is protected against epidemic diseases by vaccines manufactured by the Bureau of Science. The most outstanding accomplishment along this line was the manufacture of cholera-dysentery vaccine, of which a total of 6,310,600 doses was distributed, mostly to the Bureau of Health. In addition, large quantities of other vaccines were manufactured and disposed of. In all, the Bureau of Science disposed of 15,109,290 doses of vaccines. Among the most important of these were vaccines against smallpox, cholera, typhoid, and dysentery.

Smallpox, which used to be a tremendous scourge and caused terrible epidemics, is now little feared owing to the use of vaccine. The efficiency of this vaccine is due to a considerable extent to improvements introduced in its manufacture by the Bureau of Science. The last cholera epidemic was ended with the use of Bureau of Science vaccine against cholera. So long as vaccination is continued there should be no

further epidemics. Vaccine has also been a great agency in the control of typhoid. More recently the Bureau of Science perfected an antidysenteric vaccine suitable for local conditions and causing no painful reaction.

The Bureau of Science promotes the health conditions in the Islands in many other ways. Important among these is the examination of foods submitted by various agencies, including the Bureau of Health and the Customs. Such substances are examined to see that they meet the requirements of the Pure Food and Drug Act. Particularly important is the examination of imported canned goods, such as salmon and sardines. Some of the local products examined include ice-cream, coco-nut and other vegetable oils, meats, lard, milk, soft drinks, alcoholic beverages, bread, confectionery, fruit, vegetables, fish, sugar, molasses, soaps, cheese, dyes, flour, and cereals. Bacteriologic examinations are also made on the food handlers in Manila. Waters all over the Philippines are examined, both bacteriologically and chemically, and no waterworks project is started until the Bureau of Science certifies that the water is suitable for human consumption.

The Bureau of Science also assists the Quarantine Service in keeping out epidemic diseases. In 1933, 65,154 rats were examined for plague as a protection against the introduction of this disease in the Islands.

Better known is the anti-rabic treatment. Each treatment consists of twenty-five injections, which are furnished free. A total of 2,676 treatments were given during the year. The anti-rabic treatment is also used by city veterinarians in Manila to vaccinate dogs.

The Bureau of Science assists the Bureau of Health, the Quarantine Service, and other Government entities as well as private doctors in making diagnoses by examining specimens, such as faeces, blood, sputum, and urine. In 1933, 21,959 examinations were made. For the protection of the public the Pure Food and Drug Act of the Islands requires that the containers of drugs and biologic products be properly labelled and that the labels state accurately the constituents of the drug. Under this law drugs are collected by the board of medical and pharmaceutical examiners and inspectors and analysed by the Bureau of Science; if found to be mislabelled, they cannot be sold.

The strength of cement and other structural materials that go into the construction of buildings and the strength of the resulting concrete are very important from the standpoint of public safety. The Bureau of Science is required to test all cement used in Government structures, in buildings in the City of Manila, and the resulting concrete in these structures.

The Bureau of Internal Revenue is in charge of the supervision of weights and measures used to weigh and measure articles sold in the Philippine Islands, but the Bureau of Science carries on the examination and certification of standard weights and measures.

The Bureau works for the farmers by examining soils and fertilizers. All fertilizers sold are required to be registered in the Bureau of Science, and the Bureau of Commerce inspects fertilizers to see that the farmer gets the composition guaranteed by the manufacturer.

The Bureau also aids the farmer by investigating the cause, prevention, and remedies of plant diseases and by giving information and advice on these subjects.

The Bureau of Science is open to the public for consultation on all matters pertaining to science, and it makes examinations for the public of almost all conceivable kinds of articles. These examinations include medical specimens, cotton goods, paper, leather goods, galvanized iron, mineral oils, food products, paints, and practically anything that requires testing.

Consultations and advice are given free to manufacturers of and merchants dealing in soaps, oils, paints, dairy products, soft drinks, ice, artesian water, etc.

The researches conducted by the Bureau of Science have aided the development of industries in the Philippines, the promotion of sanitation, and the development of medicine.

Researches conducted by the Bureau of Science have resulted in the establishment of numerous industries and the improvement of a great many more, while the possibilities of still other industries have been pointed out. These include glass, paper, vitrified brick, ceramics, medicinal remedies, paint oils including lumbang, and numerous others.

Original work done by the Bureau of Science along medicinal lines has been very important. An enumeration of all of it would require much space, but one example may be mentioned here. For many years beri-beri was a cause of much infant mortality, until scientists working in the Bureau brought forward tiki-tiki extract as a remedy. Tiki-tiki extract is now made by a number of firms and also by the Bureau of Science. The Bureau's product is distributed free by the Office of Public Welfare Commissioner through its puericulture centres.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL R. N. CHOPRA, C.I.E., Professor of Pharmacology and Officiating Director, School of Tropical Medicine, Calcutta, is appointed to officiate as Surgeon-General with the Government of Bengal, with effect from the 9th September, 1935, *vice* Major-General D. P. Goil, granted leave.

Lieutenant-Colonel R. Knowles, Professor of Protozoology, School of Tropical Medicine, Calcutta, is appointed, in addition to his own duties, to act as Director of the School, *vice* Lieutenant-Colonel R. N. Chopra, appointed to act as Surgeon-General with this Government.

Lieutenant-Colonel F. A. Barker, O.M.E., Officiating Deputy Director-General, Indian Medical Service, is appointed as Officer on Special Duty in the Home Department, with effect from the 24th August, 1935.

Lieutenant-Colonel M. G. Bhandari, on return from leave, is appointed to be Superintendent and Medical Officer, Yeravda Central Prison, *vice* Lieutenant-Colonel R. V. Martin, proceeding on leave.

Lieutenant-Colonel E. C. A. Smith, Superintendent, Central Mental Hospital, Yeravda, is appointed to be a Justice of the Peace within and for the territories subject to the administration of the Government of Bombay other than the Presidency of Bombay.

Lieutenant-Colonel N. J. Holgate, O.M.E., to be Civil Surgeon, Karachi, on the expiry of his leave, *vice* Major J. E. Gray.

Major J. E. Gray to officiate as Civil Surgeon, Nasik, *vice* Mr. V. L. Sathe.

LEAVE

Major-General D. P. Goil, K.H.P., Surgeon-General with the Government of Bengal, is granted leave for 22 days, with effect from the 9th September, 1935, with permission to prefix Sunday, the 8th September and to affix the Pujah Holidays and the following Sunday to the leave.

Lieutenant-Colonel A. D. Stewart, C.I.E., Director, All-India Institute of Hygiene and Public Health, Calcutta, is granted combined leave for 28 months, with effect from the 13th September, 1935, or any subsequent date on which he may avail himself of it, preparatory to retirement.

Lieutenant-Colonel S. A. McSwiny, Officiating Professor of Obstetrics, Medical College, Calcutta, is granted combined leave for two years, with effect from the 13th October, 1935, or any subsequent date of availing.

PROMOTIONS

Brevet-Colonel to be Colonel

W. H. Hamilton, C.I.E., C.B.E., D.S.O. Dated 6th August, 1935, with seniority from 1st January, 1922.

Majors to be Lieutenant-Colonels

H. C. Tait, M.B.E. Dated 2nd August, 1935.
 W. J. Webster, M.C. Dated 16th August, 1935.
 J. C. Chukerbuti. Dated 17th August, 1935.
 A. M. Ghosh. Dated 19th August, 1935.

Captains to be Majors (provisional)

R. L. Frost. Dated 15th August, 1935.
 J. C. Drummond. Dated 22nd August, 1935.
 D. M. Fraser. Dated 25th August, 1935.
 J. F. Shepherd. Dated 28th August, 1935.

RETIREMENTS

Lieutenant-Colonel V. B. Green-Armytage, 28th July, 1935.
 Lieutenant-Colonel H. Hingston, 31st July, 1935.
 Lieutenant-Colonel A. N. Thomas, D.S.O., 7th August, 1935.
 Lieutenant-Colonel A. P. G. Lorimer, on account of ill health, 8th August, 1935.

Notes

BRITISH MEDICAL ASSOCIATION MEETING
MELBOURNE

9TH TO 14TH SEPTEMBER, 1935

*Exhibit of Burroughs Wellcome and Company
(Australia), Limited*

THE constancy with which Burroughs Wellcome and Company remain in the forefront in the application of original research and of the latest scientific discoveries to medicine was well illustrated by the exhibits of this firm. The following products are selected for special comment:—

'Wellcome' insulin is now made from crystalline insulin of 100 per cent purity and is the first commercial product thus prepared.

The recent announcement of the isolation of the new ergot alkaloid—ergometrine—by Dudley and Moir was followed, within the remarkably short space of three weeks, by the first commercial issue of several preparations of ergometrine for administration by mouth or by injection. These products had a prominent place on the exhibit, together with ergotoxine ethanesulphonate, originated and introduced by Burroughs Wellcome and Company. The use of ergometrine followed by ergotoxine ethanesulphonate would appear to be ideal for use during the puerperium.

Digoxin, a pure, stable, crystallized glucoside, isolated from the leaves of *Digitalis lanata*, was also exhibited. This glucoside discovered at the Wellcome Chemical Works, Dartford, England, is of known and definite chemical composition so that the results obtained by its use are uniformly reliable. Digoxin may be used whenever drugs of the digitalis group are indicated.

'Tannafax', a preparation for the modern treatment of burns and scalds, consists of tannic acid in a water-soluble base. It is always ready for application and is specially valuable for first-aid work.

Several preparations for use in leprosy and which were introduced as the result of work conducted in the Wellcome Chemical Research Laboratories were also to be seen, while organic arsenic and bismuth preparations were shown as examples of spirillicides. Numerous 'Tabloid' brand products were exhibited. These are characterized by exceptional purity, accuracy of dosage and reliability.

'Kepler' cod-liver oil with malt extract is a valuable dietary adjunct and contains vitamins A, B and D in their natural association. It is extremely palatable and easily digested.

A HÆMOGLOBIN SCALE

THE method of estimating hæmoglobin by means of a piece of blotting paper and a printed colour scale, against which the blood-soaked paper is matched, is admitted by most medical men to be a *very rough* method, but still it is claimed that it is better than guessing the degree of anæmia by looking at the patient's tongue, especially in India when this is often stained with *pan*. Further, it is the only method that can be completed as rapidly as timing the pulse, and it requires the minimum of apparatus; for these reasons it is probably the method that is used nine hundred and ninety-nine in every thousand times that the hæmoglobin is estimated in this country.

If this method has to be used, then the essential is to obtain a well-printed scale. The manufacturers of Idozan, a colloidal preparation with high iron content that is used largely in anæmias of the iron-deficiency type, have put up a useful hæmoglobin scale that appears to fulfil the necessary requirements; it is in the form of a neat little booklet that will easily go into the pocket, not being as bulky as the usual form of hæmoglobin scale.

The agents, Messrs. Coates and Cooper, 94, Clerkenwell Road, London, E.C. 1, say that they are prepared to send this scale to any physician who cares to apply for it.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

SOME OF THE MAJOR COMPLICATIONS IN THE TREATMENT OF SYPHILIS

By R. V. RAJAM, M.B., M.S. (Mad.), M.R.C.P. (E.)
Venereal Specialist, General Hospital, Madras

ON the subject of the complications and untoward reactions which arise in the course of treatment for syphilis, we have a considerable volume of literature, including the reports of the German and British Commissions set up to investigate them. A multiplicity of predisposing factors, dependent on the patient, on the disease, on the drug, and on the technique of its administration, have been investigated and described. These investigations have helped to some extent towards the prevention of some of these reactions, but, in spite of all this work, the inevitability of the occurrence of these reactions in a certain percentage of cases is realized by all clinicians who have any considerable experience in treating syphilis.

This paper sets forth our experience in the study and treatment of some of the major complications in the treatment of syphilis in the venereal clinic of the General Hospital, Madras, during the three years 1932, 1933 and 1934. During this period 7,160 cases of syphilis were examined and treated of which 5,575 were males and 1,585 were females including children. The treatment was outpatient and ambulatory in more than 95 per cent of the cases. The routine method of treatment adopted in the clinic is the combined or concurrent method whereby both the organic arsenicals and the heavy metals are administered simultaneously. The injections are given once a week. The route of administration of the arsenicals is intravenous in adults and intramuscular in children. The heavy metal is given by the intramuscular route. The arsenical preparation used as a routine during the greater part of the period was neo-salvarsan (Bayer) except for six months in 1933 when novarsenobillon (May and Baker) was used. The bismuth preparation was 'Hypoloid Bismuth Metal' (Burroughs Wellcome). In children one of the sulfarsenobenzene preparations was used. The dosage of the arsenicals for an adult varied from 0.3 gramme to 0.45 gramme and rarely exceeded the latter. It is not sufficiently realized by doctors in this country, and especially in South India, that the dosage scales advocated by European and American clinicians are unsuitable for the average Indian. So far as South India is concerned the average weight of the adult patient of the hospital class varies from 80 to 100 lbs. and we feel convinced the European dosage is much too heroic.

The three major complications which form the subject of the present study are:—

- I. Cutaneous reactions,
- II. Jaundice, and
- III. Haemorrhagic encephalitis.

I. Cutaneous reactions

The cutaneous reactions were the most frequently observed complication and were caused in almost all the cases by the trivalent arsenical preparations. The occurrence of heavy-metal skin reactions, though described, is so rare that it can be ruled out from the present discussion. Sixty-two cases of cutaneous reactions were seen and treated in the department. Of these five cases had developed skin trouble as the result of injections received outside from private practitioners. Table I gives the clinical classification.

TABLE I

Clinical variety of cutaneous reaction	Males	Females, including children	Total
Erythema ..	14	6	20
Severe exfoliative dermatitis	15	5	20
Mild exfoliative dermatitis	7	5	12
Lichenoid dermatitis	1	1
Fixed exanthem	1	1
Arsenical pigmentation ..	2	1	3
Arsenical hyperkeratosis ..	2	..	2
Herpes zoster ..	3	..	3

All the five outside cases were males and included two cases of exfoliative dermatitis, two of erythema and one of hyperkeratosis of the palms and soles.

Table II gives the incidence of the reactions in relation to the total number of cases and to the number of injections given.

TABLE II

	Males	Females, including children	Total
Total number of syphilis cases.	5,575	1,585	7,160
Total number of injections of the arsenicals.	19,529	5,021	24,550
Number of cases with cutaneous reactions.	38	19	57
Incidence in relation to cases.	1 in 147	1 in 83	1 in 126
Incidence in relation to the number of injections.	1 in 514	1 in 264	1 in 431

Predisposing factors

The ages of the adult patients varied from 20 to 58, the average being 35 years. There

were two children aged 5 months and 11 months in the series.

Sex.—There was a distinct relative preponderance of females showing cutaneous intolerance to treatment, but the severity of reactions were milder than in the males. This relative increase in skin reactions in the female was in marked contrast to the decreased incidence of the other major complications.

Religion.—The Hindus formed the majority of the cutaneous reactors, but they constitute 70 to 80 per cent of the patients attending the clinic. Hence, no special significance could be attached to the increased incidence among them.

Social status, diet, alcohol, etc.—It is our impression, though exact figures are not available, that 95 per cent of the syphilitic cases that attended the clinic belonged to the poorer classes who live on a bare subsistence. It is a well-known fact that the diet of the poorer class in South India consists mostly of carbohydrates with little protein and less fat. The predisposition to arsenical intoxication may be greater in these persons if one is to take into consideration the analogy of animal experiments conducted by Craven in America, who showed that dogs fed principally on carbohydrate were more susceptible to the toxic action of arsenic. He also showed that a diet rich in protein and fat afforded increased protection to the animal. In the majority of the male patients who suffered from severe arsenical dermatitis, a history of ingestion of alcohol was obtainable, and it is quite conceivable that alcohol with its injurious action on the liver may be a contributory factor in the increased severity of the cutaneous reactions, if not in their incidence.

Influence of the stage of syphilis on cutaneous reaction.—Table III gives the incidence of the cutaneous reactions in relation to the stage of syphilis for which treatment was given. In the table are included four non-syphilitic cases, all males, who had received injections outside.

TABLE III

Stage of syphilis	Males	Females	Total
Primary ..	3	1	4
Secondary ..	10	1	11
Tertiary ..	18	8	26
Latent ..	5	6	11
Congenital	2*	2
Neuro-syphilis ..	3	1	4
Non-syphilitic ..	4	0	4
TOTAL ..	43	19	62

* Children.

This table shows that among syphilitics the incidence of cutaneous reactions is greatest amongst those with late entrenched infection,

nearly 73 per cent being in this class. Apart from the increased incidence the most severe forms of exfoliative dermatitis occurred only in tertiary syphilitics. Three factors may possibly account for this:

(i) An allergic cutaneous instability induced by chronic long-standing syphilitic infection.

(ii) Injuries to the endothelium of the capillaries caused by *Spirochaeta pallida*, and intensified by the vasculo-toxic action of arsenic.

(iii) Injuries to the liver and kidneys caused by chronic late syphilis may interfere with the oxidation and elimination of the drug.

As Kolmer has rightly pointed out, the syphilitic factor should not be over-emphasized, as we had four cases of arsenical dermatoses in non-syphilitics. Another peculiarity in our series was the occurrence of moderately severe dermatitis in two children under one year of age suffering from congenital syphilis. We are not aware of any report of dermatitis occurring in such young infants mentioned in the literature on the subject. The ages of the children were five and eleven months, respectively, and both completely recovered from the attack. The father of one of these children who was receiving anti-syphilitic treatment for asymptomatic late syphilis also developed a very severe form of exfoliative dermatitis and narrowly escaped with his life. The simultaneous susceptibility of both father and child to arsenical intoxication in this instance may either be a coincidence or point to some common undetermined factor.

Relation of the number of injections to the dermatoses.—Table IV gives the number of cases which occurred after the number of injections.

TABLE IV

Number of injections	Number of cases	Number of cases in group and per cent of total	
1	1	16	26
2	2		
3	7		
4	6		
5	10		
6	5	41	66
7	8		
8	6		
9	7		
10	5		
11 to 13	4	5	8
19	1		

The largest number of reactions occurred between the 5th and 10th injections. The majority of the cases of exfoliative dermatitis developed the complication between the 5th and 7th injections. The milder cutaneous erythemas mostly occurred between the 1st and 4th injections.

TABLE V
Seasonal incidence of the reactions

January	0	9 cases
February	2	
March	2	
April	1	
May	3	
June	1	53 cases
July	8	
August	6	
September	9	
October	15	
November	8	
December	7	

This table shows the striking preponderance in the incidence of the cutaneous reactions in the second half of the year. Such a striking disparity cannot be a coincidence, but may have a definite ætiological significance. During the second half of the year it is our impression that the general health of the population is at a lower level of efficiency than during the first half. The fevers, coughs, colds and gastro-intestinal upsets seem to be more prevalent in the latter half. The rains of the north-east monsoon, the humidity of the atmosphere and the severe fluctuations of meteorological conditions are more prevalent during the second half of the year and may have some as-yet-undetermined influence on the general health of the population and indirectly on the incidence of the cutaneous reactions.

The relation of cutaneous reaction to the brand of drug used.—It is a well-known fact that the 'neo' preparations of trivalent arsenicals vary widely in their toxicity, oxidizability and therapeutic action. This variation is found not only between different brands of the drug but also in different lots of the same brand. During 1933, the largest number of cutaneous reactions, with two deaths, occurred when two different brands of the drug were used. It is possible that the varying toxicity of different preparations may have a contributory influence on the cutaneous reaction.

The factor of induced allergy.—The cutaneous sensitizing effect of technically incorrect intravenous injection, which permits a little of the drug to infiltrate the skin, may render the patient intolerant to subsequent injections of the same drug. The chances of perivenous cutaneous infiltration are more likely to occur in women in whom the veins are small and the induced sensitization may account for the greater incidence of cutaneous reactions in them. We had only one definite case in the female in whom this factor of induced sensitization due to the faulty skin infiltration precipitated a dermatitis after the subsequent injection of the same drug. The greater incidence of toxic effects arising from the administration of the sulfarsenobenzene preparations, which are usually given subcutaneously or intramuscularly, is attributed by many clinicians to this factor of induced allergy, but we have not had sufficiently large an experience

of these preparations to warrant an expression of opinion on the point, as the vast majority of the injections were given intravenously in the clinic. The occurrence of cutaneous complications after a fewer number of injections that are not in themselves sufficient to produce a cumulative action on the system may also be considered as a point in favour of induced allergy. The factor of natural hyper-susceptibility to arsenic is not proved and seems to be so rare that it is not an important ætiological factor in cutaneous reactions.

The influence of focal infections.—According to Stokes and Cathcart,¹ an allergic instability of the skin is induced by circulating bacterial proteins which are liberated from a focus or foci of infection by the administration of trivalent arsenicals and the cutaneous reaction is of the nature of an anaphylactic phenomenon. The injury to the liver and suprarenals might be contributory factors. Moore and Keidel explain the cutaneous dermatoses in a different way. They believe that bacterial anaphylaxis may be the fundamental change, that the organic arsenicals favour the production of bacterial anaphylaxis, and that these in turn by producing vaso-dilatation of the skin favour the deposit of arsenic which acts as an irritant.

The hepato-toxic hypothesis.—Hoffman propounded the theory that the liver is injured by the arsenic and loses its power of detoxicating the drug when subsequently administered, with the result that it tends to accumulate in the skin and cause dermatitis. In support of this theory a number of cases of coexisting jaundice and dermatitis have been reported in the literature. In our series there was only one case of dermatitis followed by jaundice and none of the cases of jaundice developed any cutaneous reaction.

Summary.—From the foregoing discussion of the ætiological factors, it appears that a multiplicity of causes, rather than a single one, is responsible for the cutaneous reactions of arsenical therapy. Osborne's recent investigations have shown that the trivalent arsenicals are vasculo-toxic. They injure the endothelium of the capillaries favouring the perivascular deposition of arsenic. Induced allergic cutaneous instability, brought on either by the drug itself or by bacterial proteins or by chronic syphilitic infection, may be a contributory or concomitant factor. Injury to the liver or suprarenals, the former by interfering with the elimination of arsenic, the latter by producing a deficiency of circulating adrenalin, may favour the accumulation of arsenicals around the blood vessels of the skin. The depressing effect of arsenic on the bone marrow may account for the severer reaction of the skin and very often for the fatal results.

Description of the different cutaneous eruptions.—The erythemas constitute nearly a third of the total number of reactions. They

developed usually after the second or third injection. They start with chills, malaise and pains all over, followed by an erythematous eruption which may be macular, papular, morbilliform or scarlatiniform in type. There is no lividity nor infiltrative exudation of the skin. In about three or four days the condition subsides with fine furfuraceous desquamation. Sometimes the desquamation is large and flaky

Fig. 1.—A case of severe exfoliative dermatitis.

especially on the palms and soles. Stoppage of arsenic and a few injections of sodium thio-sulphate will suffice to cure this condition. Many authorities, including Milian and Stokes, recommend the continuance of the treatment with arsenicals after the subsidence of the erythema. In our series the patients exhibited so much fear of any further injections that they defaulted from our observation. Hence we had

no opportunity of testing the possibility of continuance of the treatment.

Acute exfoliative dermatitis constituted nearly 52 per cent of the cutaneous reactions. Twenty cases were severe and twelve were mild. The incidence in relation to the number of injections and number of cases is shown in table VI, in which the two cases of dermatitis admitted from outside are not included.

TABLE VI

	Males	Females	Total
Number of cases	5,575	1,585	7,160
Number of injections.	19,529	5,021	24,550
Number of cases of exfoliative dermatitis.	20	10	30
Proportion to cases.	1 in 279	1 in 158	1 in 239
Proportion to injections	1 in 976	1 in 502	1 in 818

Though the incidence of exfoliative dermatitis was twice as frequent in women as in men, the severity of the reaction was very much less in the former than in the latter. Eighty-one per

Fig. 2.—Exfoliative dermatitis in an infant five months old.

cent of the cases of exfoliative dermatitis occurred between the 5th and 10th injections, 2 to 14 days after the last injection. In a typical case the condition starts with a severe

chill and intense itching all over the body. A diffuse livid infiltrative erythema appears on the skin and rapidly becomes vesicular or bullous in places, especially at the joint flexures, behind the ears and round the neck. There is considerable swelling of the face, particularly the eyelids and lips. The weeping eczematous condition with fissuring and crust formation makes the patient an object of misery. The patient is restless and may be so irritable that it may be difficult to obtain his co-operation in treatment. In spite of the severe shivering from which these patients suffer, fever was absent in a majority of the cases and in the early stages. Temperature of a hectic type was observed in those who developed secondary pyogenic infections. In a few of the severe and fatal cases, the patient rapidly went into a low typhoid state with a low muttering delirium. The weeping eczematous condition of the skin subsides after a variable time giving place to a dry dark-brown leathery scaly condition. The exfoliation goes on continuously and may be so abundant that the patient will be literally lying on a bed of scales. At this stage the patient rapidly loses weight. The hair and nails may be shed. The skin of the palms and the soles are the last to peel off. The mucous membranes of the mouth, pharynx, trachea, conjunctiva, vagina and intestines may share in the exudative exfoliative process. In a favourable case the patient enters on the convalescent stage, the irritability of the skin disappears, his appetite improves, and there is less and less scaling. The skin assumes a glazed, bronzed, atrophic condition. In some of our very dark-complexioned patients the skin became of a lighter tint. One patient developed a permanent vitiligo of the skin of the neck and shoulder. In some of the cases of exfoliative dermatitis who have recovered, the combined effect of emaciation, change in the colour and texture of the skin, and a certain indefinable change in the contour of the face, makes them unrecognizable by their own relatives.

Complications.—The following are the complications observed in our cases of exfoliative dermatitis :—

	Cases
Persistent diarrhoea	15
Melæna	2
Pyogenic abscesses and suppurating lymphadenitis.	6
Cellulitis and gangrene of the foot ..	1
Bed sore	1
Broncho-pneumonia	1
Jaundice	1
Albuminuria	6

Blood examination.—It is being increasingly recognized that acute exfoliative dermatitis is but a manifestation of a gross injury to the vascular system and the bone marrow. As such, a regular and complete examination of the blood for signs of bone marrow injury should form a part of the routine in the investigation and

treatment of this condition. In 23 of the cases of dermatitis a leucocyte count of the blood was performed and the following were the results :—

	Cases
Moderate leucocytosis, the increase mainly of the lymphocytes and eosinophiles.	7
Moderate leucopenia at the expense of the polymorphs.	4
Eosinophilia	15
Lymphocytosis including mononuclears	9
Transitional myelocytes	3

Duration of the complication.—The mild cases cleared up in three weeks. The severer ones lasted from 8 to 10 weeks.

Prognosis and mortality.—The prognosis of exfoliative dermatitis is always uncertain and grave. Unfavourable points in prognosis are :

1. Evidence of bone marrow injury. A drop in granular leucocytes, a rise in eosinophiles and lymphocytes, a drop in red blood cells and platelets.
2. Persistent diarrhoea.
3. Bleeding from mucous membranes.
4. Respiratory distress and cyanosis.
5. Gross and severe secondary septic infections.

The mortality statistics of different observers show a 25 to 30 per cent toll of death rate. The deaths in our cases were three, all in males one of which was an outside case.

Incidence of deaths from exfoliative dermatitis in relation to the number of cases treated. 1 in 3,550

Incidence of deaths from exfoliative dermatitis in relation to the number of injections. 1 in 12,275

Percentage of deaths in relation to the cutaneous reactions. 5 per cent

Percentage of deaths in relation to exfoliative dermatitis alone. 9.4 „

Causes of death in our series

Bleeding from the bowels and mucous membrane of the mouth ..	1 case
Intractable diarrhoea and septic parotitis ..	1 case
Gangrenous cellulitis foot ..	1 case

Lichenoid eruptions.—This is a rare and interesting form of arsenical cutaneous intolerance. There was only one case in our series. A Hindu married woman, aged 37, attended the department for pigmentation of the palms and soles. Her blood Wassermann reaction was strongly positive and she was receiving injections of neosalvarsan and bismuth. After the fifth injection she complained of itching and a dusky erythema of the limbs and face. The treatment was stopped and sodium thiosulphate injections were given. The itching and erythema disappeared after four injections of sodium thiosulphate. Three weeks after the subsidence of the skin trouble a patch cutaneous test with neosalvarsan was performed on the patient and

found negative. The treatment with neosalvarsan was restarted. Three days after the first injection of neosalvarsan she broke out with itchy, purplish, papular eruptions on the limbs, chest, back and neck. No more arsenic was given but in spite of a number of injections of sodium and calcium thiosulphate the lesions continued to progress and finally assumed a dark bluish pigmentation with lichenification. In the chest and neck the eruptions coalesced to form large irregular patches. There was no disturbance of general health and no involvement of the mucous membranes. The patient is still under observation and treatment. Auto-hæmotherapy and exposure to ultra-violet rays are being tried.

Fig. 3.—Lichenoid eruptions, post-arsenical.

The fixed arsenical exanthem.—This is another rare but interesting type of cutaneous reaction, and was observed in a female patient. A circumscribed solitary, itchy, urticarial patch developed on the inner aspect of the left thigh after each injection of neosalvarsan. The patch disappeared after a few days only to reappear after the next injection. After the fourth injection the patch did not disappear but became thickened and slightly eczematous. The weekly injections were continued till the patient finished a full course. The patch remained stationary. The patient was lost sight of after the first course of treatment.

Arsenical pigmentation, 3 cases, 2 males and 1 female.

In all the cases the pigmentation appeared after 10 to 15 injections of neosalvarsan. The

pigmentation was patchy, non-itchy and found principally on the face and neck near the hair margin. There was no increase in the melanosis when the treatment was continued. During the rest interval they tended to disappear.

Arsenical hyperkeratosis, 2 cases, males.

One was an outside case. In both the cases the condition started after three injections of sulfarsenobenzene. There was hyperkeratosis of the palms and soles with fissuring and scaling. The fissures were very painful and tender and disabled the patients from using their hands and feet. The lesions were not associated with any other cutaneous trouble.

Herpes zoster, 3 cases, males.

Two cases developed herpes zoster after the third injection and the third after the tenth injection. The herpetic vesicles developed along the course of the 8th and 9th dorsal nerves, and on the anterior and upper part of the chest wall in each of the three cases respectively. The condition was associated with a certain amount of burning pain, and disappeared in a fortnight. The treatment was continued in all the three cases without any mishap. It is doubtful whether the lesion was arsenical in origin or merely a coincidence during the treatment.

Prophylaxis of the cutaneous reactions.—It may be remembered that a certain percentage of the cutaneous accidents in the arsenical treatment of syphilis seem inevitable and do occur even in the best conducted clinics and practices. This does not mean that the clinician should spare any pains in the careful investigation of a case before treatment. In the first place, a thorough examination of the syphilitic patient regarding the condition of the skin, liver and kidneys is a desideratum in any well-conducted syphilo-therapeutic practice. Gross pathological conditions of the organs of the body are of course contra-indications to the treatment with the arsenicals, or an indication that great care should be exercised. The history of any allergic sensitivity in the patient should be elicited and noted down. The existence of any focal infection in the teeth, tonsils, prostate, etc., should be investigated and may require appropriate treatment. The vagotonic highly nervous type of patient is supposed to be a bad reactor and hence great care is required in the treatment of such a person. Smaller doses of the drug at shorter intervals rather than massive doses at long intervals should be the method of choice. After every injection and before the next injection is given the patient should be questioned as to how he fared after the last injection. Repeated chills, fevers, gastrointestinal disturbances after every injection signify intolerance and the treatment should not be blindly pushed. Itching of the palms and soles, a state of increased excitability, a feeling of apprehension and the absence of a sense of well-being, these are forewarnings

of impending cutaneous trouble. The preventive value of the patch test to determine whether the patient is likely to be sensitive to arsenic or not has not been fully investigated. In our own experience in the only case in which the test was performed a negative result did not prevent the onset of cutaneous trouble later, when the treatment was restarted. But the test is of great help in those cases of cured exfoliative dermatitis in whom the question of resuming the treatment with the arsenicals may arise. The test is performed as follows :—

0.3 gramme of the arsenical preparation which is to be used in treatment is dissolved in 1 c.cm. of water. A small square bit of lint is soaked in this solution, applied to the forearm of the patient and kept in place with adhesive plaster. After 24 hours the lint is removed and the area of the forearm examined. A positive reaction is indicated by a patch of dermatitis with vesiculation and means that the patient is sensitive to the drug.

The protective value of the simultaneous administration of sodium thiosulphate along with the arsenical drug has been disappointing in our experience. One of our fatal cases of exfoliative dermatitis was receiving injections of sodium thiosulphate along with the arsenical preparation from the very commencement of treatment. In spite of this precaution, he developed a very severe dermatitis after the 8th injection and died of excessive bleeding from the bowels. It is our opinion that sodium thiosulphate neither prevented the onset of dermatitis nor alleviated the severity of the attack.

Treatment of cutaneous reactions.—The milder cutaneous reactions respond quickly to the stoppage of arsenic and the administration of three or four injections of sodium thiosulphate. The treatment of exfoliative dermatitis, the most serious and dangerous type of cutaneous intolerance, will tax alike the resources of the doctor and nurse as well as the patience and co-operation of the patient. The patient should be hospitalized and skilled nursing instituted. As these patients with severe dermatitis suffer from chills in the earlier stage of the condition due to the effect of cutaneous vaso-dilatation, every precaution should be taken to ensure warmth. This was secured in our cases by the application of continuous radiant heat by means of electric bulbs. Scrupulous cleanliness and changing of the bed linen will prevent the grosser forms of secondary septic infection. It is a great advantage to keep the patient in an air or water bed. In the light of Craven's conclusions on the influence of diet on dermatitis, it seems advisable to put the patient on a diet rich in proteins and fats. Plenty of milk, cream and eggs constitute the chief diet. The patient should be encouraged to drink large quantities of water to aid elimination of toxic products. In view of the great frequency of diarrhoea as a complication, purgatives should be avoided.

In constipated cases a soap-and-water enema may be given on alternate days. In persistent diarrhoea we have found daily enemata of saline or potassium permanganate solution one in ten thousand more efficacious than any medication by mouth. Periodic differential blood counts during the course of the disease form an essential routine in the treatment, to gauge the severity of the affection and as an aid in prognosis.

Special therapeutic measures.—The following are the measures recommended and used :

1. The administration of sulphur-containing compounds.
2. Glucose and insulin therapy.
3. Calcium compounds.
4. Preparations of liver.

1. The compounds in use are sodium thiosulphate, intramine, contramine, thiosinamine, selvadine, and calcium thiosulphate. We have used sodium thiosulphate as an intravenous injection very extensively in our cases. Five to ten c.cm. of a ten per cent solution is given intravenously on alternate days for four to six injections. Our experience with this drug was rather disappointing. The preventive value of this drug when simultaneously administered with the arsenicals was nil in some of the cases in which we tried it, but it had very beneficial effects on the milder erythemas. In the typical exfoliative dermatitis we did not observe any good from its administration either as regards the severity of the attack or the duration. When the drug was administered continuously, milder cases of dermatitis turned into fulminating types after the fifth or sixth injection. The rationale of administering sulphur compounds in exfoliative dermatitis in which there is considerable perivascular accumulation of arsenic in the deeper layers of the skin seems questionable. In an acute explosive accident like dermatitis, sudden and rapid liberation of arsenic as insoluble sulphides may throw considerable strain on the excretory organs of the body, and this fact may account for the exacerbation of the dermatitis which we have time and again observed in the continued administration of sodium thiosulphate. On the other hand we tried calcium compounds either with or without sulphur and were satisfied with their beneficial effects. Calcium gluconate or calcium thiosulphate in 10 per cent strengths were employed in a number of cases in which the previous injection of sodium thiosulphate resulted in an aggravation of the dermatitis. The effect on the exudative and eozematous processes was striking. The skin became drier and less irritable and cutaneous infiltration and thickening lessened. A maximum of six injections (5 to 10 c.cm.) daily or on alternate days by the intravenous route is good practice. The action of calcium on various exudative and inflammatory conditions is well known. In

exfoliative dermatitis it probably acts by restoring vasomotor instability of the cutaneous vascular sympathetic system, by checking the increased permeability of the capillary walls and the inflammatory serous exudation in the deeper layer of the skin, and by indirectly decreasing the cutaneous irritability. When calcium compounds with a sulphur radicle are administered the action of calcium, combined with the detoxifying effect of the sulphur moiety is obtained, though we would consider calcium as the more important constituent.

We have had very gratifying results from the administration of liver extracts either by mouth or by injection. Continued experience convinces us that it should be placed first and foremost among the therapeutic measures in the treatment of dermatitis and other intoxications of organic arsenicals. In three of our hyper-acute rapidly-progressive cases the patients turned the corner only after the injections of liver extracts. 'Campolon', a Bayer preparation, was used in these cases. It has now become a routine in our clinic to administer liver to patients suffering from dermatitis. In those patients with gastro-intestinal irritability, the liver is given as an intramuscular injection. In the last 11 cases of dermatitis in our series where this routine was followed, there was not a single death. The action of liver on dermatitis is not well understood. It might be a form of substitution therapy but it is very likely that its beneficial effect is on the blood-forming organs, the function of which is often depressed by arsenic.

Dreyfus, Harrison and others recommend the intravenous injection of 50 per cent glucose solution with injections of insulin to fix the former in the liver in arsenical dermatitis. Our experience with this method is limited to only one recent case not included in this article and is very encouraging.

A Hindu male, aged 54 years, with tertiary syphilis, developed exfoliative dermatitis after the fifth injection of neosalvarsan. In addition to the other general measures he was given 20 c.cm. of a 50 per cent glucose solution daily for three days and 15 units of insulin was also given subcutaneously. The action on the cutaneous condition was dramatic. The exudation disappeared, the oozing dried up and the patient sat up in a week and asked for more food. No other drug was administered.

The ordinary solution of glucose is slightly acid in reaction and is likely to produce a severe rigor after intravenous injection. Harrison recommends alkalization of the solution. In view of its marked beneficial effects in our case, it deserves a more extended trial.

Local treatment.—In the acute exudative eczematous stage, the frequent application of calamine lotion was the only measure adopted in our series. The action of calamine on drying up the exudation and diminishing the intense itching is remarkable. In the later stages of

dry, leathery exfoliation daily hot baths combined with the local application of a bland oil should be the routine.

Treatment of individual symptoms.—Stomatitis requires alkaline mouth washes. Cracked painful lips should be smeared with borated glycerine. For the conjunctivitis, we recommended washing with boric lotion and instillation of a few drops of ZB lotion. For the exfoliative ileo-colitis with diarrhoea, daily bowel washes with saline or potassium permanganate lotion should be given. For tracheo-bronchitis with dry troublesome cough, a sedative expectorant is indicated. If there is any sign of aplastic anaemia, bleeding from the gums, nose or bowel, transfusion of a matched blood should be immediately given. During the convalescent stage the food intake should be increased and vitamin B in the form of brewer's yeast was found very effective in our cases in toning up the skin and in alleviating the purplish oedema of the feet and legs from which these patients frequently suffer.

Effect of dermatitis on the Wassermann reaction.—We have not been able to follow up the majority of patients after they were discharged. In a few cases under observation there was a temporary reversal of the Wassermann reaction, but in four to six months the reaction became positive. The question whether the treatment with organic arsenicals may be resumed in a patient who suffered from exfoliative dermatitis should be answered in the negative though some recommend the use of a different arsenical preparation to the one which caused dermatitis. In this connection the value of the patch test with the particular preparation proposed to be used is very great. Figure 4 is a photograph of a positive patch test in a patient who suffered from a severe attack of exfoliative dermatitis six months before. Though he had no clinical evidence of syphilis his blood Wassermann was positive at the time of the patch test. It is safer to treat such patients with either mercury or bismuth.

Fig. 4.—Positive patch test in the forearm in a patient who suffered from exfoliative dermatitis six months before.

Medico-legal considerations.—The possibilities of medico-legal trouble in these cases should

be borne in mind. A patient who was a victim of dermatitis as the result of treatment may haul up his doctor before a Court of Law for heavy damages. The doctor should satisfy the court that he took all reasonable precautions and exercised skill and care in the treatment of the patient. Unfortunately in our country the unrestricted sale of these arsenical preparations, the indiscriminate use of these powerful drugs, both by the qualified practitioner and by an army of unqualified quacks, compounders, and ward-boys, present a serious menace not only to the suffering public but also to the good name of the most outstanding therapeutic discovery of the twentieth century.

II. Jaundice

Jaundice takes the second place in the incidence of major complications in the treatment of syphilis.

Incidence.—There were 21 cases of jaundice in the three years' record of treatment. All the cases were benign and treated as outpatients. The incidence is given in table VII.

TABLE VII

	Males	Females	Total
Total number of cases treated.	5,575	1,585	7,160
Total number of injections.	19,529	5,021	24,550
Total number of cases of jaundice.	18	3	21
Proportion to cases.	1 in 310	1 in 528	1 in 341
Proportion to injections.	1 in 1,085	1 in 1,674	1 in 1,169

Age and sex.—The ages varied between 20 and 40, the average being 30. Unlike dermatitis there was a preponderance of males over females.

Jaundice in relation to the stage of syphilis

	Cases
Secondary syphilis ..	13
Tertiary syphilis ..	3
Latent syphilis ..	2
Early neuro-syphilis ..	2
Non-syphilitic ..	1
TOTAL ..	21

The striking preponderance of jaundice in secondary syphilitics under treatment is significant—a finding that may be a factor in the aetiology of the condition.

Jaundice in relation to the number of injections of neosalvarsan.—Nine cases developed jaundice after less than four injections, nine developed it between the 7th and 10th injections, three between the 10th and 20th injections.

Interval between the last injection and the appearance of jaundice.—The shortest interval was two days and the longest was 2½ months.

Five cases developed jaundice within a week, 6 cases from 1 to 3 weeks, and 10 cases from 4 to 10 weeks after the last injection.

Yearly and seasonal incidence.—Nearly 57 per cent of the cases of jaundice occurred during 1934. Neither the number of cases of syphilis nor the number of injections given during 1934 could account for the increase. The complication was more frequently observed during the humid and rainy months of the year, though this seasonal distribution was not so striking as in the case of dermatitis.

Aetiology.—The aetiology of jaundice in relation to syphilis under treatment is a most obscure problem. Various conflicting and divergent views are advanced:

I. The jaundice may be caused by syphilis alone. We have not come across even a single case of jaundice in an untreated syphilitic patient, though 7,160 syphilitic patients have passed through the clinic. In any case the purely syphilitic aetiology of the condition is outside the present discussion as all the cases of jaundice in our series developed the complication after treatment with the arsenicals.

II. Jaundice may be due to the combined action of the syphilitic infection and the arsenical remedy. Such a combination may act in several ways:

(a) A focal Herxheimer reaction may be set up in a case of asymptomatic syphilitic hepatitis after the injection of one or more doses of the organic arsenical with resulting congestion and jaundice.

(b) Milian of Paris is the staunch exponent of the view that jaundice is of a nature of a hepato-recurrence, analogous to the neuro-recurrence, and is caused by inadequate treatment with the arsenicals. The surviving spirochaetes are awakened into activity after the cessation of treatment and cause hepatitis and jaundice. His arguments in favour of this view are: (i) that jaundice occurs commonly at the end of six to eight weeks after the cessation of treatment which is the favourite period likewise for neuro-recurrence, (ii) that it is often associated with cutaneous or mucosal relapse, and (iii) that the jaundice disappears under further arsenical therapy. Milian has cited 30 cases of jaundice in inadequately treated syphilitics, where vigorous continuation of the treatment with the arsenicals has resulted in rapid and complete cure of the complication.

(c) The liver cells may be slightly damaged by the spirochatal toxins and may become more predisposed to the toxic action of the arsenicals.

III. The purely arsenical causation of jaundice has its own advocates. It is contended that the incidence of jaundice has greatly increased after the introduction of arsenicals in the treatment of syphilis, that jaundice has been known to occur in non-syphilitic patients as the result of the injection of the arsenical and that certain lots of the drug are more likely

to produce jaundice than others. The 'neo' preparations are alleged to be more 'icterogenic' than the salvarsan preparations. In support of the arsenical theory may be cited the report of the British Medical Research Council (no. 55, 1920) on eight fatal cases following the use of '606'. Pathological examination of the liver in these fatal cases revealed gross degenerations and necrosis, lesions resembling those caused by another hepato-toxic drug tri-nitro-toluene.

IV. The view advocated by Stokes and Ruedemann and supported by certain British observers is that jaundice in treated syphilitic subjects may be neither due to syphilis nor to the medicament but may be caused by incidental intercurrent infection of an undetermined nature. The occurrence of jaundice in a syphilis clinic may be part of an epidemic prevalence of the condition in the general population. Further, jaundice may be more prevalent during certain months of the year when there may be a general increase in the respiratory, gastro-intestinal and other forms of infection. The experience of the Mayo clinic is cited as a point in favour of this theory. Stokes and Ruedemann state that jaundice was a rare complication in the treatment of syphilis in the Mayo clinic from August 1916 to August 1918; from August 1918 to July 1920 there was a tremendous increase in the incidence of jaundice though the brand of the drug and the technique of administration remained the same throughout the four years. The increased incidence could not be accounted for by any Herxheimer reaction or hepato-recurrence as all the patients received thorough treatment. It is stated that the arsenic may be a predisposing factor by inducing a mild hepatitis but the exciting cause is an organismal infection of unknown aetiology.

Summary of aetiological considerations.—As in the case of arsenical dermatitis a multiplicity of causes seems to be at work. From our series of cases, certain inferences may be drawn:

1. All the cases of jaundice in our series were mild, lasted from one to four weeks and completely recovered from the attack. A few of them returned to the clinic after the rest interval and continued treatment without any relapse of jaundice.

2. Nearly 62 per cent of the cases who developed jaundice were suffering from early secondary syphilis at the time of the commencement of the treatment. It is possible that a proportion of these cases might be due to hepatic Herxheimer reaction.

3. There was no constant relationship between the total dosage of the drug and the incidence or severity of jaundice. Jaundice was equally common after four injections as after seven to ten injections. There were only three cases of jaundice between ten and twenty injections. These facts seem to be against a purely arsenical aetiology.

4. Only 24 per cent of the cases were cases of early jaundice developing within a week after the last injection. The rest were cases of late jaundice. Judged from the interval of time, a large percentage of the cases seems to be due to hepato-recurrence, the result of inadequate treatment. In this connection it may be stated that the majority of syphilitic patients in the clinic default after a few injections when the active manifestations of the disease disappear. Amongst the few patients who underwent thorough treatment lasting from 18 months to 2 years, no jaundice was observed.

5. The increased incidence of jaundice during the rainy months of the year and the marked preponderance of this complication in 1934, as compared to the preceding two years, may point to an extraneous factor probably infective or epidemic in the causation of the complication.

Clinical manifestations.—The majority of patients with jaundice presented the following symptoms and signs: malaise, anorexia, nausea and itching of the skin. A few patients complained of slight chill and fever. The urine contained bile in all the cases. The stools were not examined. There was discomfort in the upper abdomen and slight enlargement of the liver in 10 per cent of the cases. All the cases were ambulatory.

Van den Bergh reaction.—This was carried out in 15 of the cases and the following are the results. In every case the indirect reaction was positive; in 9 cases there was a positive direct, in one case a direct biphasic, and in 5 cases a negative direct reaction.

The quantitative estimation varied from 3.2 units to 17.2 units.

Treatment.—Injections of the arsenicals were stopped. Four to six injections of sodium thio-sulphate, five to ten c.cm. of a ten per cent solution, were given on alternate days. The patients were given glucose by mouth and saline purgatives once in 2 or 3 days. In two cases of deep jaundice, injections of cytotropin were tried with satisfactory results. Under treatment, the jaundice cleared in from two to four weeks in all the cases.

III. *Hæmorrhagic encephalitis*

Hæmorrhagic encephalitis is easily the most formidable, fatal, and least unpredictable of all the major catastrophies in the treatment of syphilis. In the great majority of cases, this complication arises from the administration of the organic trivalent arsenical compounds and very rarely from heavy-metal therapy.

Incidence and predisposing factors.—The incidence varies widely in the experience of different clinicians, but fortunately it is the rarest of all the more serious complications of arsenical therapy. During the three years from 1932 to 1934, ten patients were treated in the clinic for this complication. Of these, four patients had received injections outside from

practitioners, and were brought to the hospital with fully-developed encephalitis, so that only six cases were really hospital cases. Among the ten, nine were due to arsenic and one to bismuth, the latter being one of the outside cases. The incidence of this complication in relation to the patients and to the total number of injections was as follows:—

Number of patients treated in the department.	7,160
Total number of arsenical injections given.	24,550
Number of cases of encephalitis ..	6
Proportion in relation to cases ..	1 in 1,193
Proportion in relation to injections ..	1 in 4,091

Age.—Young robust adults are more frequently affected. The youngest in our series was 17 years, the oldest 32 years, the majority under 30.

Sex.—There was a preponderance of males over females. Among the ten cases, nine were males and one female.

Analysis of the cases

	Number of cases
Sero-positive primary syphilis ..	2
Secondary syphilis ..	1
Latent syphilis with gonorrhoea ..	1
Tertiary syphilis with skeletal manifestation.	1
Latent syphilis with warts ..	1

The four outside cases were all non-syphilitic with a negative Wassermann. The first case had received sulfarsenol injections for chaneroid and bubo. The second patient was given solusalsvarsan and the condition for which the patient was given this injection could neither be discovered nor could be elicited from the relatives. The third patient had received an injection of novarsenobillon for chronic gonorrhoea. This patient had come to our clinic three weeks before his death. On examination it was discovered he had a chronic posterior urethritis, but no evidence of syphilis, clinical or serological. He was advised to undergo treatment for gonorrhoea, but he wanted salvarsan injections and persisted in spite of the negative Wassermann and absence of any evidence of syphilis; the injection was refused. He went to a gullible practitioner and had an injection of '914'; he was brought to the hospital with acute fulminating encephalitis and died within six hours of admission. It seems as if the patient went deliberately in search of death. A fourth case had received bismuth salicylate injections for chaneroid. His Wassermann was negative. He developed typical encephalitis ten days after the second intramuscular injection of bismuth salicylate. From this analysis it is obvious that this complication may supervene in syphilitic and non-syphilitic alike and that a heavy metal like

bismuth may occasionally be a factor in the production of this complication.

Influence of dosage and number of injections on the complication.—In the clinic cases the dosages of the arsenical preparations never exceeded 0.3 gramme. The dosages of the outside cases could not be definitely ascertained.

Three patients developed the complication after the first injection, four after the second, and three after the third.

Regarding the particular brand of drug used, four patients had injections of neosalvarsan and three had injections of novarsenobillon, intravenously, and one patient each had sulfarsenol, solusalsvarsan, and bismuth salicylate intramuscularly.

The conclusions from these findings are:

(a) The dosage of the drug employed has not affected the production of this complication.

(b) The complication sets in after a few injections or within the first three injections.

(c) Our figures may appear that it is more frequent after the intravenous injection of neosalvarsan or novarsenobillon than after the intramuscular injection of sulfarsenol or solusalsvarsan, but it should be remembered, so far as the clinic cases are concerned, that both neosalvarsan and novarsenobillon were used in the clinic to the almost complete exclusion of the other preparations, and that the patients who received sulfarsenol or solusalsvarsan were outside cases. Hence, a comparison to the detriment of the former drug is not justifiable.

Interval between the injection and the development of the complication

Days after last injection	Number of cases
4	3
5	3
7	2
8	1
10	1

The average interval works out as six days after the last injection.

Clinical picture.—The modes of onset vary. In three of the patients the onset was with severe headache, mental confusion, and inarticulateness. In two cases pyrexia of 104° and 105°F., with a noisy delirium, and disorientation was the first symptom. In five cases the onset was with epileptiform convulsions. In one of the pyrexial cases the patient had a diffuse scarletiform erythema of the face and chest. Whatever the mode of onset, the patient becomes rapidly comatose, and convulsions, clonic or tonic in type, recur at varying intervals.

Examination of the fully-developed case.—The patient lies comatose. There is generalized

THE TREATMENT OF LOBAR PNEUMONIA WITH INTRAVENOUS INJECTIONS OF ALCOHOL

By ILAHI BAKHSII, M.D. (Lond.), M.R.C.P. (Lond.)
CAPTAIN, I.M.S.

and
A. T. ANDREASEN, M.R.C.S. (Eng.)
CAPTAIN, I.M.S.

Indian Military Hospital, Jhelum, Punjab

THE treatment of lobar pneumonia still remains a difficult problem in spite of the hordes of research workers toiling devotedly in this field all over the world.

So far, the sheet-anchor of the pneumonic patient has been good nursing and rest, drugs having persistently failed us. It is gratifying* to know that digitalis is so little used nowadays by the modern physician to combat heart failure in pneumonia. Morphia is still a great friend of the physician but must be used cautiously; its administration after the third or fourth day of the disease is the surest means of hastening a fatal issue.

Oxygen therapy has been advocated for the relief of cyanosis, and various methods of administration, including elaborate oxygen tents, have been invented, but one doubts its material benefit once the cyanosis is marked. Even its early administration, when the cyanosis is very slight, has not reduced the mortality appreciably in our experience. Those who have any experience in pneumonia know how futile all these measures prove once a patient starts going down hill.

Anti-pneumococcal serum has not given the good results at one time expected of it, and the expense entailed in its preparation forbids its general use. Recent work by Sutcliffe and Finland (1934) shows the application of specific serum therapy to pneumonia to be even more limited than was previously supposed. These authors state that serum can only be employed to any purpose in one out of ten cases suspected of pneumonia.

Modern research has therefore utterly failed to solve this difficult problem, and to give the physician a weapon wherewith to combat this dreaded disease. For most of us the issue depends upon good nursing and the hope that no complication will occur.

The oral administration of alcohol in the treatment of pneumonia has been practised since time immemorial. Medical opinions still differ as to its efficacy. While we do not hesitate to give small doses of brandy or champagne to a case of failing heart we believe that the routine administration of alcohol in pneumonia, although rendering the restless patient momentarily peaceful, does more harm than good by

*[Note.—At the risk of disappointing our contributors we feel that we must point out that, despite recent criticism of the use of digitalis in pneumonia, there are still many excellent physicians who still use digitalis in pneumonia and consider it of great value. EDITOR, I. M. G.]

lowering his resistance on account of its specific action on the liver cells.

Intravenous alcohol has been used by various European physicians in a variety of diseases, such as cancer of the lungs, puerperal sepsis, subacute endocarditis, but it was Landan, Feigin and Bauer (1931) who first used it in pulmonary suppurations. Their theory was that intravenous alcohol, instead of being taken up by the liver cells and detoxicated, as in oral administration, went straight to the right side of the heart from whence it was taken by the pulmonary circulation to the lungs. The curative effect of alcohol in their cases of post-pneumonic pulmonary suppuration was due, in their opinion, to the selective affinity of alcohol for the reticulo-endothelial cells in the pulmonary tissue, where it exerted its bactericidal power. They gave small doses of insulin to protect the liver from any damage which might be done by an overflow of alcohol from the pulmonary circulation.

We first tried this treatment on a case of pulmonary abscess complicating pneumonia, and the result was so satisfactory that we were curious to know what effect intravenous alcohol would have on an uncomplicated case of lobar pneumonia. We believe that this is an experiment hitherto untried by any other workers.

Technique of injections

We employed, in the cases quoted, a solution of 20 per cent alcohol in sterile normal saline. The dose used varied from 20 c.cm. to 25 c.cm. per day, in the average-sized patient. We later found that the strength of the solution could be increased to 33 per cent without causing any more reaction than previously. In only one case did we have to give two injections of 12 c.cm. and 10 c.cm. per day on account of constant rigors which single doses of 20 c.cm. produced. In all the other cases the reaction to the injection was slight, and limited to a feeling of chilliness about 20 minutes to three-quarters of an hour after the injection.

Subcutaneous infiltration due to faulty technique in puncturing the vein produced momentary pain running up the arm. Slight induration without suppuration at the site of injection was the only sequel we observed when by mischance the needle either slipped out of the vein or transfixed it.

Case records

Case 1.—G. H., recruit, aged 18, admitted for pain in the right chest, cough and fever of one day's duration.

Condition on admission.—Temperature—101° F., pulse—102, respiration—24, general condition good, alae nasi working. Cyanosis—nil. Lungs—impaired percussion note over the back of the right lower lobe with pleuritic rub over the eighth rib in the right mid-axillary line, with diminished air entry, broncho-vesicular breathing and sub-crepitant râles. Sputum—tenacious and rusty.

Treatment.—Saline aperient, Dover's powder at night for the first three days. Cataplasma to the chest and sedative expectorant mixture.

2½ inches by 1½ inches over the back of the left lower lobe. Painful cough had developed with rusty sputum containing numbers of pneumococci. Alæ nasi working with slight dyspnoea; no cyanosis; white blood cell count 12,600 (poly. 78 per cent, lympho. 18 per cent, l. mono. 3 per cent, eosin. 1 per cent).

Treatment.—Twenty-one cubic centimetres of 20 per cent alcohol solution injected intravenously. Some coughing occurred during the administration of the alcohol, but a few minutes later the patient said that the pain had gone from his chest and he was feeling sleepy. On waking an hour later, the patient had no pain in either abdomen or chest, and his cough was markedly less irritating. The patient slept well that night.

1st May. Twenty-two cubic centimetres of 33 per cent alcohol solution administered. A slight rigor took place 20 minutes later. The patient had an excellent night.

2nd May. Lung signs remained unchanged, without any increase in the area of consolidation previously mentioned. The injection of alcohol (33 per cent) was repeated. The rigor was this time very slight. The physical signs diminishing; previous patch of consolidation is now occupied entirely by râles, and the breath sounds are becoming vesicular.

3rd May. The patient himself asked for his injection this morning, stating that he wished the injections continued as he felt so much better after the previous one. The injection was repeated.

4th May. The condition much improved, dyspnoea has disappeared. The signs of consolidation and râles have now completely disappeared. There is no cough or sputum. Injections continued daily with further improvement in the general condition. White blood cells—10,400.

6th May. The temperature rose only to 99°F.

8th May. The temperature normal. The patient sitting up with no signs in the chest or abdomen.

A rapid and uneventful convalescence followed.

Case 6.—R. S., Sepoy, aged 18. Admitted on 16th May, 1935. Sudden onset of pain in right chest twelve hours previously with cough and fever. Temperature—104°F., pulse—120, respiration—30. General condition good. Dyspnoea moderate; no cyanosis; signs of early pneumonic congestion in right lower lobe of lung; cough dry and painful without sputum. No apparent abnormality in the heart. Urine:—acid, specific gravity 1025, albumin ++, deposit containing a few white blood corpuscles and red blood corpuscles with some granular casts; no sugar or other abnormality present. Blood slide for malarial parasites negative. White blood cells—27,000 (poly. 75 per cent, lympho. 20 per cent, l. mono. 3 per cent, eosin. 2 per cent). Total red blood cells 4,287,500, hæmoglobin 80 per cent, colour index 0.9. Symptomatic treatment was instituted.

18th May. Condition the same. Sputum rusty, thick and tenacious.

19th May. Chest pain worse, cyanosis evident, signs of consolidation have appeared over the back of the right lung; character of the urine unchanged.

Treatment.—Injection of alcohol (20 c.cm. of 33 per cent) commenced. Slight coughing occurred during the injection but no rigor. The effect was dramatic, the pain in the chest disappearing and the patient falling soundly asleep within two hours of the injection. He had a peaceful night with a good deal less dyspnoea.

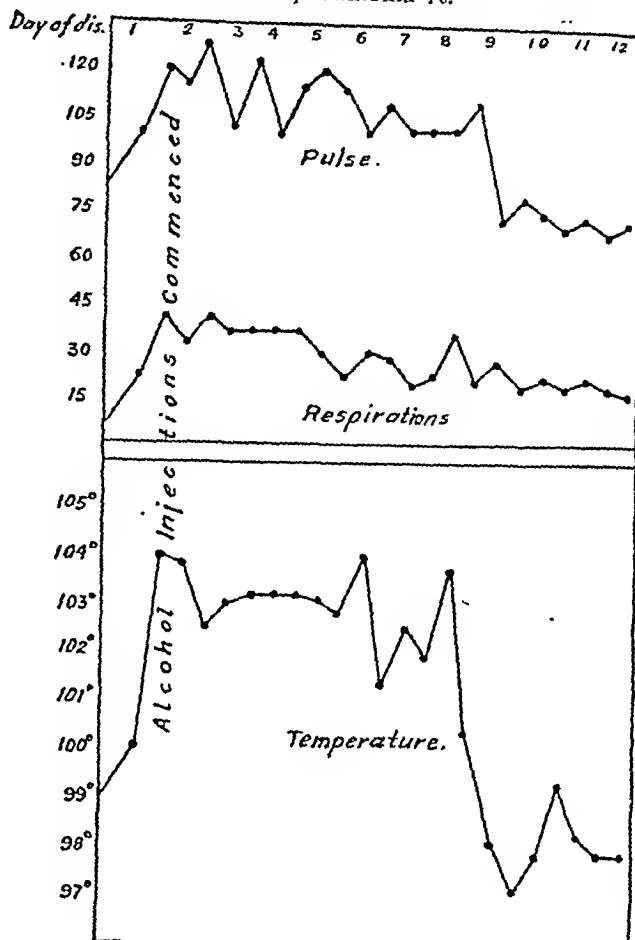

21st May. Cough and sputum practically negligible. Urine total quantity 29 ounces, alkaline, specific gravity 1031, albumin nil, casts a few, number very much decreased. No red blood nor white blood corpuscles. Injections of alcohol continued daily without any reaction such as rigors or coughing.

22nd May. Sleeping well and feeling well with very little cough. Lung signs remained unchanged. White blood cells—12,400. The albumin reappeared in the urine in very slight quantity, but no other abnormal content.

23rd May. Crisis occurred with further improvement in the general condition.

24th May. Urine clear of albumin.

Case 6, Sepoy, R. S. Admitted 16th May, 1935.
Lobar pneumonia rt.

25th May. A slight rising of temperature to 99.4°F. but the progress otherwise very satisfactory.

26th May. Resolution is rapidly taking place. From this date on no more injections were given, and convalescence was rapid and uneventful.

Discussion

The first case, one of pulmonary abscess, is included in this paper because it was our first case in which intravenous alcohol was tried. The results were so encouraging in a case which was clinically in a very bad condition that we were of opinion that perhaps, by early institution of alcohol treatment in all cases of pneumonia, we might avoid many of the complications of this disease.

In connection with the subject of alcohol intravenously administered in pneumonia, one of us (A.) calls to mind a case of double pneumonia, treated last year. The patient had arrived at its eleventh day with consolidation present in both lungs with bubbling râles, temperature—104°F., pulse—130, irregular and of low tension, respiration—55, cyanosis marked with cold sweating extremities, with no signs of a crisis or resolution by lysis being about to take place. All the signs of impending dissolution were present; the patient was severely toxic, and delirium had been present for three days. The urgent question of treating the patient had

to be faced. An intravenous injection of glucose 10 per cent and brandy half an ounce in about 50 c.cm. of sterile normal saline was given twice during the eleventh day, and once on the twelfth and thirteenth days. The effect, which we at that time ascribed to the food value of the injection, was dramatic. The patient became quiet, the respiratory distress was relieved and, after a slight rigor, the temperature began to fall, and continued to fall until it reached normal on the thirteenth morning. The patient had, by this time, quite regained his normal mental state and from then on made a good recovery.

We now think, in view of the six cases quoted above, that the beneficial effect of the injection in this apparently hopeless case was due not to the food value so much as to the specific action of the alcohol.

We think the following points worthy of note. Some of these are difficult to describe on paper but were so striking clinically that they must be recorded.

(a) *Pain*.—Within an hour of the injection, in every case, there was sufficient decrease in the intensity of the pain in the chest to allow the patient to sleep comfortably. It had completely disappeared within 48 to 72 hours of the first injection.

(b) *Cough*.—After slight stimulation during the injection in some cases, there was steady decrease in the coughing. This was accompanied by a change in the character of the sputum. There was a decrease in the amount and a change from thick, rusty, pneumonic sputum to clear non-viscid watery matter within two to three days of the first injection. In those cases where injection was begun before the sputum had become rusty, it never developed this character, but very soon became watery and easy to expectorate.

(c) *Dyspnoea and cyanosis*.—Cyanosis remained entirely insignificant throughout the course of the disease in those cases where the injections were commenced from the first or second day of disease. In the majority of cases, the respiration rate was lowered and the dyspnoea much reduced.

(d) *Pulse rate*.—The pulse rate was slightly lowered and, in case 3, it remained surprisingly low considering the temperature, rarely rising above 88 for a temperature of 102°F. In case 6, which was complicated by acute nephritis and the treatment with alcohol was not commenced until the fifth day, the pulse remained well below the 110 level after that day.

(e) *Temperature*.—There was a rise of temperature more or less, after each injection, the rise being less and less as the patient's condition improved. It was remarkable, however, that the temperature remained raised until the crisis occurred at the eighth or ninth day, just as in an untreated case of pneumonia, although perhaps the general height of the temperature

was not so high as it would have been otherwise.

(f) *Consolidation*.—Arrest of the process of consolidation in these cases treated from the start of the disease was a most remarkable and outstanding feature. The congestive stage gradually regressed, so that by the time the crisis occurred the involved lobe was almost free from any signs of pneumonia. In cases 2 and 6, where alcohol was not commenced until the fifth day of the disease and where consolidation had already set in, the rapid resolution was noteworthy. Resolution in a non-alcohol-treated case takes from 12 to 15 days to be completed, whereas in these cases it was complete before the second day after the crisis.

(g) *The leucocyte count*.—Except in case 2, where the count rose from 8,500 to 12,800 after the first injection, there was a gradual decrease running parallel with the regression of the lung signs and the improvement in the general condition of the patient.

(h) *Course of the disease*.—In cases 2 and 6, where the injection was given on the fifth day of the disease, the crisis occurred on the eighth and ninth days, respectively. In cases 3, 4 and 5, the injections were commenced on the second day of the disease and the crisis occurred on the 8th, 9th and 8th days, respectively. Thus the course of the disease, from the rise of temperature on the first day to the fall on the eighth or ninth day by crisis, was the same in cases treated with alcohol, in those partially treated with alcohol, and in those not treated at all by alcohol. The complications, i.e., lung abscess and acute nephritis, were beneficially affected by the alcohol.

(i) The subjective condition of the patient was immediately changed from that of the acute distress of the pneumonic patient to one of ease and sleep. The patients themselves so felt the benefit of the injections that they themselves asked for their injections, looking forward to the relief which always followed each injection and which increased from day to day.

Although no conclusion can be drawn or hypotheses offered we feel that we have to hand a new method for the treatment of pneumonia worthy of further investigation and trial.

As cases occur so we are continuing our investigations and hope that in the near future we shall have available necessary arrangements in order that certain collateral laboratory investigations may be undertaken.

The above treatment is now being applied by one of us to post-anæsthetic and post-operative lung complications.

Summary

A new method of treatment for pneumonia is put forward, six cases are described, and the effect of intravenous alcohol, as observed in these cases, is discussed.

ATEBRIN TREATMENT IN MALARIA

By D. C. HAY, M.R.C.S., L.R.C.P.

A. E. SPAAR, F.R.C.S. (Edin.)

and

H. L. LUDOVICI, L.R.C.P. & S., L.S.T.M.

Kandy

As medical practitioners who have used the new synthetic drug, atebirin, in the treatment of malaria, both parenterally and orally, since January this year, we feel we would be doing a service to the public, and to the profession, by reporting our experiences with it.

We have a large outdoor practice, both amongst villagers and town residents; in the former case, we are not able to follow up all our treatments, but we receive confirmation of the good results of the atebirin treatment, from the attendances at the dispensary and requests for injections of the drug, from villagers coming from the same locality as those who have already been treated. In the case of town patients, and pupils of colleges and schools, we keep in touch with them all, and are able to confirm the good results that have followed.

In other cases, where we cannot maintain personal contact ourselves, we have the statements of friends of our patients, so that, on the whole, we exercise a certain amount of control over as large a number of cases as private practitioners can hope to do.

Since January this year we have treated over 3,500 cases by injection with atebirin di-hydrochloride, or atebirin musonate. In this series we have not had a single case of collapse after injection, and no deaths attributable to the drug. Cases of mental excitability after treatment with the drug have been extremely rare, about five per thousand. In such cases the condition is readily controlled by sedatives, such as the bromides and chloral, and eliminants such as citrate of potash, combined with glucose administration; but in view of the fact that we have seen mental excitability approaching insanity, as a result of malaria, in cases which have had neither atebirin nor quinine, we cannot solely attribute this symptom to the use of atebirin. Occasionally, patients complain of

(Continued from previous page)

The main effects are:—

Pain and cough are immediately relieved.

The consolidation is arrested and regresses.

The patient's distress vanishes and he sleeps well, and

The 'defences' of the body are apparently not interfered with.

bad headaches after the drug, also restlessness and insomnia following the first injection, which symptoms disappear after the second injection. In a few instances, we have noticed plentiful crops of sudamina with itching of the skin, all of very temporary duration, till satisfactory excretion of the drug takes place, as evidenced by the discoloration of the urine. Instances of irritability of the stomach and vomiting of bile have occurred after oral treatment, but this we cannot put down to the use of atebirin, as these disabilities arise in cases of malaria treated with other drugs, or in untreated cases, in forms known as the 'bilious remittent', and algid types. We are of opinion from our prolonged use of atebirin, that any temporary disabilities, such as we have mentioned, are more than counter-balanced by the dramatic results obtained from its use. In our experience both salts have proved extremely efficacious, but we have used somewhat smaller doses than those advocated, and in all cases we have supplemented the parenteral treatment with subsequent oral administration.

As to dosage, we use for male adults injections of 0.15 gramme of the di-hydrochloride, and repeat this dose in 24 hours. This is followed by oral treatment of two tablets a day for six days, bringing the total of atebirin administered to 22½ grains (1.5 grammes) for the whole course, which is equivalent to a tablet taken three times a day for five days, as recommended by various writers.

In the case of females, or weak and debilitated males, we use two injections of 2½ tablets each of the di-hydrochloride and follow it up with ten tablets orally, two a day for five days. We have found this sufficient in the great majority of cases to prevent relapses. Previously-treated patients do come back at intervals of 5 or 6 weeks with a return of temperature but in view of the fact that they reside in heavily-infected localities, the probabilities are that they have been re-infected. It is not possible to make blood examinations of all cases in a dispensary practice, but we have often followed up our injection treatment by examining blood films after the second injection. We have rarely seen any ring forms after the third or fourth day and any such appeared in fragmentation, of quarter and half rings. After the fifth day, even after an excitant injection such as adrenalin, we have failed to discover parasites in the blood.

Blazé and Simeons, in their paper in the April number of the *Indian Medical Gazette*, assess the curative dose at 9 grains (0.6 gramme) and while this may be perfectly correct from the view-point of mass treatment, it would not appear to meet the needs of private practitioners in our position. In nearly all the instances in which we have given the drug in the doses prescribed by these writers, we have had our patients coming back after 10 to 14

days with relapses or re-infections. This has led us to supplement the parenteral treatment with the oral, up to $22\frac{1}{2}$ grains, which seems to confer an immunity for at least a month and in many cases for a much longer period; this is all that can be expected with patients living in heavily-infected areas.

A total dosage of $22\frac{1}{2}$ grains seems to be a safe limit for adults, although in resistant cases we have increased the dosage by 9 grains, prolonging the treatment accordingly. Whether occasional resistance is due to the inability of the patient to produce antibodies, or to the recalcitrant nature of a certain type of parasite, we cannot say. In a few cases which did not respond to atabrin we have not hesitated to give quinine.

In very few cases where the temperature had not come down after the second injection, we have given a third injection of 4 c.c.m. (2 tablets of 0.75 grain each); but we wish to emphasize the fact that these were rare exceptions, while in a considerably greater number of cases the opposite had occurred, namely, one injection sufficed to reduce the temperature; in these latter cases (where one injection reduced the temperature), there was a good deal of sweating.

In a number of cases where a tonic and stimulant appeared indicated, we have followed up our treatment with 'plasmochin silver tonic' with excellent results. We do not otherwise use plasmochin.

Pregnant-uterus.—We have used atabrin in pregnant cases with the happiest results. Uterine contractions and premature labour, as observed after the administration of quinine, were entirely absent.

Spleen.—The effect of atabrin in large-spleens is truly remarkable.

Kidney.—In a case of pyelitis, with blood and pus in the urine, atabrin was injected, owing to a concomitant malaria, with very satisfactory results.

MENTAL DERANGEMENT IN MALARIA CASES TREATED BY ATEBRIN-MUSONATE INJECTIONS

By LYN UDALAGAMA

Medical Officer, Atebrin-Musonate Centre, Narammala, Ceylon

MENTAL excitation, psychoses and other forms of temporary insanity following the oral administration of atabrin have been described by various writers, including Kingsbury (1934). Disordered mental conditions are now well recognized sequelæ of the treatment of malaria

(Continued from previous column)

Pain and abscess.—Pain at the site of injection is negligible, and most patients never complain at all. We have, in our series of cases, never had an abscess, nor has a single case of tetanus occurred. We may mention that we have used atabrin injections on a child 21 days old, with a very large spleen; complete recovery followed.

Cerebral cases.—Cases of cerebral malaria, brought in in an unconscious condition, have responded marvellously to intravenous injection, two tablets of the di-hydrochloride being found sufficient to effect a return to consciousness.

Toxicity.—As regards the toxic effects of the drug, we would like to cite one case we had, in which after an injection of 0.15 gramme of the di-hydrochloride, the patient confessed to the doctor that he had already swallowed 10 oral tablets on that day, in his desire to shake off the fever quickly. He suffered no ill-effects from the big dose and was at his work the next day.

As regards atabrin musonate, we use a smaller parenteral dose than that used by Blazé and Simeons. We give adults parenterally half the quantity recommended by them, and follow it up with oral treatment to bring the total dose up to $22\frac{1}{2}$ grains (1.5 grammes). The following is the table of dosage adopted by us:

	Hydrochloride			or	Musonate			plus Oral treatment following either		
	Number of injections	Number of tablets in each injection	Total in grains		Number of injections	Number of ampoules in each injection	Total in grains	Tablets daily	Days	Total grains by mouth
Adults ..	2	3	$4\frac{1}{2}$		2	$1\frac{1}{2}$	$4\frac{1}{2}$	1×2	6	18
Children—										
up to 1 year ..	2	$\frac{1}{2}$	$\frac{3}{4}$		2	$\frac{1}{2}$	$\frac{3}{4}$	$\frac{1}{2}$		
1 to 2 years ..	2	1	$1\frac{1}{2}$		2	$1\frac{1}{2}$	$1\frac{1}{2}$	$\frac{1}{2}$	6	$4\frac{1}{2}$
2 " 3 " ..	2	1	$1\frac{1}{2}$		2	$1\frac{1}{2}$	$1\frac{1}{2}$	$\frac{1}{2}$	5	$3\frac{3}{4}$
3 " 5 " ..	2	$1\frac{1}{2}$	$2\frac{1}{4}$		2	$2\frac{1}{4}$	$2\frac{1}{4}$	$\frac{1}{2}$	8	6
5 " 8 " ..	2	2	3		2	2	3	$\frac{1}{2} \times 2$	6	9
8 " 10 " ..	2	2	3		2	2	3	$\frac{1}{2} \times 3$	5	$11\frac{1}{2}$
								1×2	5	15

with atabrin tablets, and numerous cases have been seen in Ceylon during the recent epidemic. The onset of the symptoms generally occurs towards the end of, or immediately after, the usual course of 15 atabrin tablets, *i.e.*, after 1.2 to 1.5 grammes of atabrin have been taken by the patient.

Atabrin musonate became available in Ceylon towards the end of April 1935. The standard form of treatment with this preparation, for an adult patient suffering from malaria, is two intramuscular injections each equal to 0.3 gramme of atabrin, with an interval of 24 hours between injections.

It was hoped, in view of the much smaller dose of atabrin given parenterally, 0.6 gramme as contrasted with 1.5 grammes when given orally, that many of the unpleasant effects of atabrin by mouth, such as headache, abdominal pain, and staining of the skin, would be avoided and that mental symptoms also would be absent. Unfortunately this has not proved to be the case and the following description, therefore, of seven cases of temporary mental derangement which developed in a series of 644 cases who received injections of atabrin musonate at a field treatment centre at Narammala, between the 21st and 30th May, 1935, is of interest. The patients were villagers who for several months previously had been suffering from attacks of malaria and many of them had fever when the injections were given. Blood examination in the area, shortly before the treatment was started, showed that approximately 80 per cent of the malaria was benign tertian and 20 per cent subtertian.

To avoid any possibility of accident all the patients presenting themselves for treatment were carefully examined and only selected patients received the injections. Patients who gave evidence of nephritis, advanced hookworm disease, toxæmia associated with pregnancy or who were very debilitated or anæmic were treated by other means. All patients were given food before and after injections and rested for an hour or so before returning to their homes. I have to thank Dr. D. B. d'Alwis, the inspecting medical officer, Central Province, to whom it was my privilege to have been associated in the field treatment with atabrin musonate of 644 patients, and also to thank the Director of Medical and Sanitary Services for the kind permission given to me to publish the records of these cases.

Case 1.—U. B. male, aged 12 years.
Last injection at about 10 a.m. on the 28th May, 1935.

Onset of mental symptoms at about 12-30 p.m. on the same day, *i.e.*, about 2 hours later.

Duration from 12-30 p.m. on 28th May to 6 a.m. on 29th May, *i.e.*, about 17 hours.

Nature of mental symptoms.—Restlessness, irrational speech and behaviour, abusiveness, loss of memory.

Dose of atabrin musonate.—0.2 gramme in one injection.

Detailed history.—He left his residence at about 8 a.m. after a morning meal of rice. He walked about a mile to the centre where the injections were given. At the centre he had a bowl of *conjee* before the injection and a bowl of soup after. He was also given sweets after the soup. While at the centre he did not feel anything unusual. He waited here about an hour before starting back to his home. When he was about 100 yards from his residence, at about 12-30 p.m., he felt giddy and faint. He had no heaviness of the head nor headache at the time. From the time he felt giddy to the time he arrived at the rest-house at about 4-30 p.m. his memory is a blank. He remembers nothing whatever that took place during this interval. I questioned the Buddhist priest with whom the child lives as to the condition of the child during this time. According to him he was very restless, running about the compound, abusing people, not recognizing his relations nor his friends, spitting on people and refusing food. The priest tells me that it was with great difficulty that he was able to restrain the child. The child was brought before us at about 4-30 p.m. at the rest-house. The boy remembers only the rest-house. He walked through the bazaar but does not remember any part of the journey. At the rest-house when we saw him he was excited but quiet. He was not violent nor did he show any peculiar behaviour. He was given an ounce of chloral and bromide draught to be taken home and given if he became restless again. This was given at bed-time and he had a good night's rest. When he got up the next morning he was perfectly normal and felt nothing unusual. The child remembers all the incidents from the time he came to the rest-house at 4-30 p.m. till he went to bed. He was quiet and nothing unusual occurred from this time onwards. There was no family history of insanity, epilepsy nor anything of note. Personal history—nothing of note.

Case 2.—M., female, aged 8 years.
Last injection given at 12 noon on the 21st May, 1935.
Onset of mental symptoms at 3-30 p.m. on the same day.

Duration from 3-30 p.m. on 21st May to the morning of 23rd May, *i.e.*, about 36 hours.

Nature of mental symptoms.—Delirium, headache, restlessness, excitement, incoherent and incessant speech and irrational behaviour.

Dose of atabrin musonate.—0.16 gramme on 20th May; 0.16 gramme on 21st May.

Detailed history.—This child was an inmate of the temporary hospital receiving treatment for malaria. She had been here on several occasions. After the second injection of 0.16 gramme of atabrin musonate given on the 21st May she developed a high temperature at about 3-30 p.m. We saw her at 4 p.m. and found her in a delirium. She complained of a severe headache, the eyes were injected, she was restless, and talking peculiarly and incoherently. Her face was flushed. She was quiet but

muttering the whole time. The next morning her temperature subsided but her behaviour was still peculiar in that she used to laugh at nothing, and look at people with a coquettish look. She was disobedient. The very next day all these symptoms subsided and she was normal.

Case 3—A. N., female, aged 25 years.

Last injection given at 11 a.m. on 21st May, 1935.

Duration from 12 p.m. the same day to 6th June, i.e., 17 days.

Nature of mental symptoms—Complete loss of memory, no maniacal symptoms at all, indifference to her surroundings and her own children, fainting giddiness, heaviness of head, incoherent and incoherent speech.

Dose of atabrin musonate—0.3 gramme on 21st May; 0.3 gramme on 22nd May.

Detailed history.—The injection was given about 11 a.m. after a bowl of *congee*. She also had a bowl of soup after the injection. She stayed here for about an hour before she started for her residence. The distance she had to cover was about 2 miles to her home after the injection. When she had gone about a quarter of a mile she felt giddiness and general weakness, and she noticed that she was swaying from side to side like a drunkard. She felt worse on her arrival at home and went straight to bed. She did this because she felt so bad that she couldn't even raise her head.

The giddiness was extremely severe at this time. Later she was informed by her relations that she behaved peculiarly after she went to bed in that she talked incoherently, laughing at nothing and for no reason at all. This cleared up the next morning and she came back for her second injection. After her second injection up to the time of her departure for her native place at Kukulnape, which was three days later, she had only heaviness of head and general weakness of her lower limbs. While she was at her native place she was dazed, indifferent to her surroundings, uninterested in her own children and relations when they spoke to her. She couldn't think for herself. Even at this time her appetite was good. There was complete loss of memory of past events. This state lasted for about 5 days. Then she started bathing and applied some oil to her head. This was done for about 8 days. Gradually her heaviness of head and loss of memory disappeared from the time she started bathing. At the end of 8 days she found herself normal once again in her head. She has no complaints now. There is no family history of insanity, epilepsy or any other nervous disease, nor any alcoholic history.

Case 4—J. F., male, aged 45 years

Last injection given at 11 a.m. on the 24th May, 1935. Duration from 8 p.m. on 26th May to 7th July, i.e., 1 month and 11 days.

Nature of mental symptoms—Giddiness, lack of concentration of mind, sleeplessness, loss of memory, delusions, abusiveness, violent, maniacal delirium.

Dose of atabrin musonate.—0.3 gramme on 23rd May; 0.3 gramme on 24th May.

Detailed history.—The injection was given at about 11 a.m. after a bowl of *conjee*, and a bowl of soup was given after the injection. He rested here for about half an hour before he left for his home which is about half a mile from the centre. In the morning when he came for the injection he had a cup of tea with 'hoppers' at about 8 a.m. On his return he had no midday meal but had a meal at about 4 p.m. On the 24th May he was perfectly normal. The next day, he had a bath at about 11 a.m. followed by a midday meal and rested for a time in bed. He got up at about 4 p.m. and felt a constriction in the sides of the neck (over the sterno-mastoid muscle and the posterior part of the neck). He felt giddy and saw everything around him turning round and round. His vision was blurred. He rubbed some oil on the neck and head and felt a little better. Then he started writing a charm which is his normal vocation. In this he made some mistakes which he says never happened in his experience before. He made a second attempt and found mistakes in this also, according to his judgment at the time, and he put this off to the next day. He had his evening meal at about 6 p.m. and went to bed at about 9 p.m. He could not sleep at all that night. He walked about the house the whole night because the constriction in his neck was increasing. He applied the medicinal oil again. Still sleep would not come. He heard the cock crow. Then he fell off to sleep and was asleep till about 8 a.m. He got up and had his morning tea. He took up his work again but found he could not do it as he couldn't concentrate his mind on the work. He was still feeling giddy and, thinking it would pass off, he bathed a little longer than usual. He had no midday meal. This was on the 26th. He had only a cup of tea that day till his evening meal which was taken at about 4 or 5 p.m. After his meal he came to the bazaar to earn a few cents for the next day and returned home at about 7 p.m. The lamps in the house were lit at the time he returned. A little later he refused a plate of rice given him by his wife as he thought the *sambol* would not agree with these injections he had had, and so had a cup of tea instead and retired to bed. His story from here onwards is very inaccurate but he remembers occasional incidents that took place. He remembers the police arriving and taking him to the station. His memory seems to be very poor from that evening after he retired to bed. The narrative of the events from this time onwards is taken from his wife who lives with him. After about 2 minutes of his retiring to bed he got up and went for a call of nature. He returned to bed again and got up after about 10 minutes and answered a call of nature once again in the sleeping room itself. This had never been done before. Then he called for a chew of betel. He started talking incoherently and incessantly.

He started chanting something which could not be understood. His wife questioned him as to what was the matter. She wanted to open the door to get some help but he would not allow it and threatened to kill her if she opened it. His attitude towards his wife and children was peculiar in that he wanted them to do various purposeless things such as laugh at nothing, sing, dance, etc. He became uncontrollable and violent. The noise in the house at that hour attracted the attention of the people living near about and they informed the police. The police arrived immediately—it was about midnight—and took him to the station. He has a vague idea of his coming to the police station that night. He was taken before the district judge of Kurunegala the next day and remanded to the 'house of observation'. This was on the 27th. Late in the evening when we heard of it Dr. d'Alwis and I went immediately to see him in the Kurunegala police station awaiting removal to the house of observation. He was most violent, abusive and talkative. He refused to take any meals or drink anything. He had delusions that some people had done him a great injustice. He recognized Dr. d'Alwis at once. His memory to all these happenings is a complete blank. The next thing he remembers is the 2nd of June in the house of observation. He says he remembers it because he saw it in big figures on the wall calendar. From that time onwards his memory gradually came back. Now he is normal once again but one looking at him would notice that he is not still what a normal person should be. He denies any history of insanity, alcohol, addiction to opium, ganja or legium.

Case 5.—S., male, aged 30 years.

Last injection at about 10-30 a.m. on the 23rd May.

Onset of mental symptoms at about 12 noon on the same day, i.e., 1½ hours after.

Duration from 12 noon on 23rd May to date.

Nature of mental symptoms.—Giddiness, loss of memory, incoherent speech, irrational behaviour, irritability of temper, melancholic and sentimental.

Dose of atabrin musonate.—0.3 gramme on 22nd May; 0.3 gramme on 23rd May.

Detailed history.—The patient had his bowl of *conjee* before the injection which was given at about 10-30 a.m. on the 23rd May and a bowl of soup after. After the injection he rested at the centre for about half an hour before starting back for his home. He had to walk about 5 miles to his village. When he had gone about 3½ miles he went to a *boutique* and had some bread and tea. He left the *boutique* and went about half a mile when he felt giddy, and a general weakness overtook him and there was a humming noise in his ears. He arrived at his home at about 1 p.m. He went straight to bed as he felt ill and weak. The giddiness and weakness and the humming noise in his ears was increasing fast. When he was in bed he felt that he was becoming worse. He started a rigor. He attempted to drink

some water which he could not do, due to his condition at the time. He felt his whole body drawn up and found difficulty in breathing. Then he felt he was becoming unconscious. He couldn't hear or understand what was happening around him. He is unable to say how long he was in that condition. He was unaware of the people going in search of the doctors at Naram-mala. He does not remember acting strangely, running about the place, talking incoherently and refusing food. His memory is blank to these incidents. After some time he became gradually conscious to what was happening around him. When Dr. d'Alwis visited him at about 10 p.m. he was quite conscious. He remembers his visit. He had no sleep at all that night. He cannot account for it. Then the next morning he had a severe headache, this had been only mild the previous evening, heaviness of head, blurring of vision. He is very irritable and loses his temper for the slightest thing. Brooding over his troubles which are non-existent, the whole day and night; his powers of assimilating anything read is greatly diminished. His affection and anxiety towards his children has greatly increased. He has become very sentimental. Even now in my presence he started crying for no apparent reason. He is very morose and melancholic. He has not made much improvement in his mental condition even to date. He was not violent at any time. He has delusions that a great calamity has befallen him and his family.

Family history of epilepsy in his mother.

Personal history.—History of *parangi* when he was a boy for which he received *salvarsan* during the time of the *parangi* campaign. He has taken two injections of N.A.B. at the Negombo hospital during the course of the last two weeks and he feels much better generally, including his mental condition, since then.

Case 6.—L., male, aged 57 years.

Last injection on the morning of the 21st May, 1935.

Onset of mental symptoms on the evening of the 21st May; was admitted in a collapsed state to the temporary hospital.

Nature of mental symptoms.—By the 28th May, the patient was admitted to the Dambadeniya hospital in a dazed condition. He was indifferent to his surroundings according to the D. M. O., Dambadeniya. He was conscious but answered questions with great difficulty. He died after a few days of his discharge from the hospital from mere exhaustion. He also developed an abscess on the right gluteal region.

Dose of atabrin musonate.—0.3 gramme on the 21st May; 0.3 gramme on the 22nd May.

Case 7.—P. A., male, aged 35 years.

Last injection at about 10 a.m. on the 27th May, 1935.

Onset of mental symptoms at about 10-15 a.m. on the same day; duration about 8 days.

Nature of mental symptoms.—Giddiness, loss of vision temporarily, sleeplessness, loss of memory, indifference to his surroundings, lack of concentration of mind, unable to think, forgetfulness. He was violent and abusive.

THE ETHERINGTON-WILSON TECHNIQUE OF INTRATHECAL NERVE-ROOT BLOCK

By A. T. ANDREASEN
CAPTAIN, I.M.S.

Indian Military Hospital, Jhelum, Punjab

SINCE the appearance in February 1934 of an article by Etherington-Wilson in the proceedings of the Royal Society of Medicine, on a new and rational technique of spinal anaesthesia, I have studied the method, and applied it to all cases where spinal anaesthesia was used.

For more than a year have I waited for the appearance of an article giving the experience of some of the leading surgeons with this method, but I have waited in vain; it is for this reason that I am putting forward my own very small experience with the method.

Those of us practising surgery in the tropics, where anaesthesia is a difficult problem, on account of the shortage of good anaesthetists, the temperature, the usual bad condition of the patient coming to operation, and other factors, realize the importance of having always to hand a reliable, rational and easily controlled method of spinal anaesthesia.

In the short series of cases appended I have found the above method to fulfil all the claims made for it, and for this reason perhaps these few notes will be of use.

Technique (after Etherington-Wilson)

The principle involved is simply to allow a light solution to ascend the vertical spinal canal, timing it to reach certain levels.

Etherington-Wilson found by experiment that the rate of ascent of a hypobaric solution in a normal vertical spinal canal from the third lumbar space to the fourth dorsal vertebra was the same as in a glass tube containing cerebro-spinal fluid and of equal length and bore.

Thus the solid contents of the spinal canal have approximately the same braking effect, as the greater amount of cerebro-spinal fluid in the glass tube has, by reason of the greater mixing, and the consequent approximation of the baric properties, of the two fluids.

In general the three types of spinal anaesthesia required are:—low—from the needle in the third lumbar space to the first lumbar nerve rootlets, medium—from the needle in the third lumbar space to the tenth thoracic nerve rootlets, high—from the needle in the third lumbar space to the fifth thoracic nerve rootlets. It

Dose of atebirin masonale.—0.3 gramme on the 26th May; 0.3 gramme on the 27th May.

REFERENCE

Kingsbury, A. N. (1934). Psychoses in Cases of Malaria following Exhibition of Atebrin. *Lancet*, Vol. II, p. 979.

is sufficient to know whether the individual is short, five feet or less, average height, five feet eight inches to five feet ten inches, or tall, six feet and over. The average distances for these three types of anaesthesia are six inches, nine inches, and 13 inches respectively, and one inch added or subtracted, as the person is tall or short, supplies the corrected distance which the fluid must travel to produce the given type of anaesthesia.

As a result of his studies he states: 'It does not seem possible that a light solution like pereinine can ever reach the higher subarachnoid spaces by direct ascent, in an intelligently conducted procedure. I am convinced that after the adoption of the Trendelenburg position of ten or fifteen degrees when using pereinine, it is quite impossible for the light mixture of pereinine and cerebro-spinal fluid, which has been allowed to ascend to a certain level beforehand, to diffuse any higher'.

There is absorption of pereinine solution during the whole time that it is ascending the canal. Therefore there is an ever-decreasing amount to ascend higher. The pereinine mixes with the cerebro-spinal fluid and therefore there is the ever-increasing dilution of the pereinine as it ascends higher.

In rough and uncontrolled injections currents are bound to be set up, and these undoubtedly account for many of the cases of failure to obtain the required amount of anaesthesia. With the vertical technique, using slowly-injected pereinine, a steadily rising and well-mixed area travels up the whole length of the spinal canal to the level required without setting up any undesirable currents.

I do not propose to go further into Etherington-Wilson's experimental work; I cannot too strongly recommend those to whom the method may appeal, to read carefully and study the original communication.

Practical details

Apparatus:—20 c.cm. ampoule pereinine, 1:500 solution, 1.003 specific gravity.
20 c.cm. syringe to fit the lumbar puncture needle,
gallipot for pereinine solution,
a basin containing slightly acidified water at 100°F.,
a tiltometer, if available,
sterilized gloves,
small syringe for local anaesthesia, with needles,
intravenous saline apparatus,
ephedrine gr. 1½, carbon dioxide and oxygen, if available, and
Coramine 5 c.cm.

Into the dish of acidified water the large syringe, lumbar puncture needle, and gallipot are put ten minutes before the arrival of the patient.

I have never used a tiltometer, but find that an ordinary pocket protractor serves the purpose.

Preparation

As for general anaesthesia, if there is time, glucose is given liberally up to within two hours of operation. A good sedative should be given the evening before; a basal drug should not be used. The lumbar region should be as carefully prepared as the actual field of operation.

One hour before the operation the patient is placed comfortably on the stretcher or trolley, in a darkened room. The ears are plugged with cotton-wool and an intramuscular injection of scopolamine gr. 1/100 given. Talking to and touching the patient is now forbidden. Deep sleep is to be avoided, only somnolence is required. Occasionally, where necessary, I have given a further dose of scopolamine, gr. 1/200, half an hour later.

Everything must be absolutely ready in the theatre before the patient is brought in. The patient is raised to a sitting position on the edge of the table and an injection of ephedrine gr. 1½ given whilst the surgeon is preparing to do the lumbar puncture.

When working single-handed, I follow the routine here given:—During the patient's last half hour in the darkened room, the theatre arrangements, instruments, etc., are checked. The surgeon scrubs up and prepares himself. The patient is sent for. At the moment of the giving of the injection of ephedrine the gallipot of percaïne is prepared and the large syringe set in order. The novocaine and small syringe are also arranged for local anaesthesia of the skin and deeper structures in the region of the third lumbar space. This gives time for the ephedrine to have effect. The site is prepared with iodine and the local anaesthetic injected. Lumbar puncture is performed; as soon as cerebro-spinal fluid flows the stylet is reinserted and the needle corkscrewed a few more millimetres into the canal to make sure that the injection is into the canal only.

The attendant now makes the patient assume a vertical position, and the percaïne solution is injected at the rate of 10 c.cm. in not less than 15 seconds at a regular speed. At the same time as the surgeon commences the injection he says 'go' and an assistant counts the seconds aloud on his watch, but in a quiet voice. A certain number of seconds are allowed to elapse before the patient is laid down in the Trendelenburg position.

Average doses and times (for operations of approximately one hour)

Low—10 c.cm. percaïne 20 seconds upright.
Medium—12 c.cm. percaïne 30 seconds upright.
High—15 c.cm. percaïne 40 seconds upright.

After the injection has been given and the patient laid in the correct position, the surgeon may again scrub up and change his gown and gloves, whilst waiting for the percaïne to take effect.

It is quite unnecessary to turn the patient, using this method.

There is no fall of blood pressure for 60 or more seconds after the injection of the percaïne so that the vertical position is quite safe for the period required for the solution to mount to the required level.

When the technique has been mastered it is found that much smaller quantities of percaïne can be used and yet the same levels attained.

If the technique laid down above is rigidly followed, consistently good results are obtained.

Failure to obtain the required anaesthesia may be due to:—

- (1) Injecting too cold a solution.
- (2) Not making sure of being in the canal.
- (3) Not acidifying the water in which the instruments are rinsed before use.
- (4) Not waiting a sufficient length of time in the vertical position.

The following is a record of 14 consecutive cases who were anaesthetized by this technique; 1 in 1,500 percaïne solution was used in all cases:

Case 1., aged 48. Many attacks of X-ray showed six stones in gall-bladder. Prepared in usual manner; pre-operation medication with scopolamine. Drowsy when brought to the theatre.

Fifteen cubic centimetres percaïne. Forty seconds in vertical, 10° Trendelenburg with pillow under lower dorsal region.

Kocher's incision. Operation time—28 minutes. Anaesthesia lasted 2 hours 15 minutes. Anaesthesia level—nipple line. Blood pressure: immediately before lumbar puncture (ephedrine already given) 90/140. No fall registered for 4 minutes.

After effects—nil.

Case 2. Perforated gastric ulcer.—C. D., aged 27, admitted as emergency. No history could be obtained, either before or after operation, of any dyspepsia. Twelve hours perforated when admitted. No preparation, apart from subcutaneous 20 per cent glucose solution, 20 c.cm. into each pectoral region.

Twelve cubic centimetres percaïne. Forty seconds in vertical, 10° Trendelenburg with small pillow under each of lower ribs. Right paramedian super-umbilical incision. Operation time—20 minutes. Large perforation with wide indurated, friable area surrounding. Inversion of ulcer not possible. Omental strip graft used to close perforation. Small drain placed in mid-line 1½ inches below umbilicus. Anaesthesia lasted 1 hour 10 to 15 minutes. Anaesthesia level—slightly below nipple line. Pulse remained steady at 110 throughout the proceedings.

Case 3. Stone in left ureter and anuria.—K. S., aged 29. Called to see patient who had pain in left side, of three days' duration. Had not passed urine for more than 12 hours. History of previous attacks of ureteric colic on right and left sides. Removed to hospital. Condition very poor generally, thirst, headache and vomiting. Catheter in bladder produced no urine.

Unprepared except for 50 c.cm., 20 per cent glucose in saline under pectorals.

Twelve cubic centimetres percaïne. Forty seconds in vertical, 10° Trendelenburg position.

Left pararectal. Operation time—1 hour. Anaesthesia lasted 1 hour 20 minutes. Anaesthesia level—about level of seventh rib in front.

After effects—difficult to distinguish between those due to type of anaesthesia and those due to suppression of mine, etc.

Case 4. Ruptured spleen.—G. H., aged 24, admitted to hospital from roadway, where he had fallen whilst getting out of a tonga. Thin, pale individual with much pigmentation of malar regions and tongue edges. Pulse small and very rapid. Respiration—sighing, restless and in pain on left side, under ribs.

Unprepared except for morphia gr. 1/6, saline and glucose 20 per cent 50 c.c.m. under pectoral.

Thirteen cubic centimetres percaïne. Forty seconds in vertical. Left pararectal incision. Splenectomy—large friable, chronic malarial spleen. Much free blood in abdomen. Time of operation—15 minutes. Anaesthesia lasted 1 hour. Anaesthesia level—just below nipple line.

After effects—some itching on the table.

Case 5. Ankylosis right knee.—M. A., aged 38, admitted with severe flexion deformities in both legs due to rheumatoid arthritis. Much wasting of leg muscles. General condition good. No pain in any part of the body. Chest free from disease. Prepared in usual manner for operation on right knee.

Six cubic centimetres percaïne. Twenty seconds in vertical, 10° Trendelenburg position.

Kocher's operation for excision of the knee joint performed. Operation time—35 minutes. Anaesthesia lasted 50 minutes. Anaesthesia level—pubis in front. No fall of blood pressure.

After effects—nil.

Case 6. Septic arthritis left knee.—H. L., aged 30, village coolie, admitted severely ill. Temperature—105, pulse—120, respiration—20. Large fluctuant swelling left knee joint region. Fluctuation extended up to the middle of the thigh. The man had been ill for three weeks, and came for treatment on account of rapid extension recently of painful area of thigh. Immediate amputation through upper limits of left thigh was performed, and the flaps left open. Twenty cubic centimetres anti-streptococcal serum given intravenously before operation.

Six cubic centimetres percaïne solution. Twenty-five seconds in the vertical, 10° Trendelenburg position. Operation time—approximately 20 minutes. Anaesthesia lasted 1 hour.

After effects of anaesthetic—nil.

Case 7. Hydrocele and inguinal hernia.—M. J., aged 29, admitted to hospital and prepared in the normal manner.

Ten cubic centimetres percaïne. Thirty seconds in vertical, 10° Trendelenburg position. Operation time—15 minutes. Anaesthesia lasted 1 hour and approximately 10 minutes. Anaesthesia level—not quite to umbilicus.

No severe fall as pulse remained good throughout.

After effects—nil.

Case 8. Vesical papilloma.—I. M., aged 28, female, admitted for hematuria. Cystoscope showed small apparently non-malignant papilloma to the centre and above right ureter.

The bladder was opened suprapubically and the small growth excised. Patient was prepared in a normal manner.

Ten cubic centimetres percaïne. Thirty seconds in vertical, 25° Trendelenburg position. Operation time—20 minutes. Anaesthesia lasted 1 hour approximately. Anaesthesia level—umbilicus.

After effect—was catheterized twice daily for two days, before power to empty her bladder returned.

Case 9. Prostatectomy.—J. M., aged 58, admitted with retention of urine. After relief an enlarged prostate was found. The patient was prepared for operation in the usual way.

Ten cubic centimetres percaïne. Thirty seconds in the vertical, 30° Trendelenburg position. Supra-pubic prostatectomy performed.

Operation time—35 minutes. Anaesthesia lasted 1 hour.

After effects of anaesthesia—nil.

Case 10. Caesarian section.—M. S., aged 26, admitted during her seventh month of pregnancy with jaundice, oedema of the legs and vulva. Marked albuminuria. Mitral stenosis of long standing. After two weeks of treatment condition improved, but the jaundice never quite disappeared, nor the albuminuria. In view of this, Caesarian section was performed at the middle of the eighth month. A living male child was delivered and the mother steadily improved and was finally discharged cured.

Twelve cubic centimetres percaïne. Thirty-five seconds in the vertical, 10° Trendelenburg position. Anaesthesia level to costal margin. Operation time—20 minutes. Anaesthesia lasted 1 hour 15 minutes.

After effects—nil.

Case 11. Hysterectomy.—M. O., aged 45, admitted for increasing and irregular uterine bleeding. On examination, an enlarged soft uterus was found. No glands palpable. Curettage had had only a very temporary effect upon the bleeding. The patient was prepared and hysterectomy performed.

Ten cubic centimetres percaïne. Thirty seconds in the vertical, 25° Trendelenburg position. Anaesthesia level—umbilicus. Operation time—10 minutes. Anaesthesia lasted 1 hour.

After effects—nil.

Case 12. Intestinal obstruction from band.—G. M., aged 30, female, brought from village on account of persistent vomiting. Patient found with much-distended abdomen, feeble pulse, extremely toxic, not having passed faeces or flatus for 48 hours. Intravenous saline and glucose given, laparotomy performed.

Twelve cubic centimetres percaïne. Thirty-five seconds in the vertical, 10° Trendelenburg position. Anaesthesia level—costal margin. Operation time—20 minutes. Anaesthesia lasted 1 hour.

After effects—nil.

Case 13. Perforated appendicitis.—H. C., aged 23, male, admitted with abdominal pain of two days' standing. The pain disappeared suddenly just after completion of examination of the patient. The patient was not prepared.

Ten cubic centimetres percaïne. Thirty seconds in the vertical, 10° Trendelenburg position. Anaesthesia level—umbilicus. Operation time—25 minutes. Anaesthesia lasted 1 hour.

After effects—nil.

Case 14. Strangulated prolapse of rectum.—K. B., aged 40, male, admitted with large gangrenous prolapse of rectum, apparently caused by large internal piles. Patient was not prepared.

Resection of the gangrenous mass was carried out.

Ten cubic centimetres percaïne. Thirty seconds in the vertical, 10° Trendelenburg position, and lithotomy position.

Operation time—25 minutes approximately. Anaesthesia lasted 1 hour, and reached the level of the umbilicus.

After effects—nil.

I am indebted to the Director, Medical Services, India, for kind permission to publish this article.

A Mirror of Hospital Practice

HYDATID CYST IN THE BROAD LIGAMENT

By SATYAPRIYA NOZUMDAR, M.B. (Cal.)
F.R.C.S. (Eng.)

Honorary Surgeon, Purulia Sadr Hospital

A YOUNG woman, aged 22, nullipara, came to the hospital for treatment of 'lumps in the stomach', of which three were in the epigastric and right hypochondriac regions and a large one in the pelvis. According to her history (and she seemed very definite on this point) the abdominal lumps had been there since she was 5 or 6 years old. The pelvic tumours had been noticed about five months ago, since when she has been having irregular uterine hæmorrhages.

On examination, three abdominal tumours were found, one large, about the size of a small coconut, and two smaller ones. They were fairly movable and connected with each other and could be pulled down to the umbilicus—but slipped back to the epigastric region on release. They were soft and cystic.

The pelvic tumour, felt through the abdominal wall, was slightly movable, and very large, nearly filling up the whole of the hypogastric and both iliac regions. It was tense, irregular and lobulated and no thrill was felt.

The patient's general condition was rather poor—but she was not anæmic.

The diagnosis seemed to lie between an ovarian sarcoma, with extensions or secondaries in the upper abdomen, a parovarian cyst, or a case of tuberculous salpingo-oophoritis.

On vaginal examination, a great deal of the vaginal wall was found prolapsed, owing to the great intrapelvic pressure of the tumour. The uterine body was completely merged into the tumour and only the tip of the cervix could be felt very high up behind the pubis. The tumour completely filled the whole pelvis and part of the vagina—so that no other information could be elicited by vaginal examination.

Considering the amount of mobility of the tumour, a laparotomy was undertaken under spinal anæsthesia, to ensure good relaxation.

The abdominal cysts were easily shelled out. The large one was in the transverse meso-colon and the smaller were attached to the under surface of the liver—but had a loose peritoneal attachment, which gave no difficulty in extraction.

The pelvic tumour, however, was much larger than anticipated and, owing to its position in the broad ligament and adhesion to the rectum, extremely difficult to take out. The uterine muscle was completely incorporated in the tumour and it was found impossible to save the uterus. The tubes and ovaries were free. The greatest difficulty in the extraction was in the lower part of the tumour, where it had encroached on the vagina to such an extent as to lie within about two inches of the vulval outlet. The sac was firmly adherent to the lower part of the rectum, so that the lowest portion had to be left *in situ*, to prevent injury to the rectum—but the rest of the tumour with the body of the uterus incorporated in it was taken out. The ovaries were left intact.

The cut end of the sac wall was sutured and an incision made from its lowest point into the vagina and a drainage tube put in.

There was a great deal of shock after the operation owing to so much peritoneal handling and pulling—but after a stormy convalescence, the patient is now almost recovered, three and a half weeks after operation.

The interesting point about the case is the rarity of hydatid cysts in the pelvis and the presence of the three quite separate tumours in the upper abdomen, which, the patient is convinced, existed there as long as she can remember. The contents of all the cysts were the same, so the question remains which are the primary and which the secondary tumours.*

A CASE OF MALARIA WITH ACUTE MANIA

By N. C. BHATTACHARJEE

Medical Officer, Kurigram Subdivision

On the 17th July last, a male, aged about 24 years, suddenly developed an attack of acute mania needing physical restraint. I was called in to see the man and found him with the following symptoms:—

The patient had to be controlled in bed by four attendants; he was talking foolishly but articulated distinctly; his eyes were shut and he resisted their being opened; Babinski's and Kernig's signs were negative. On enquiry I learnt that he had had a mild attack of fever a few months back, which may have been malaria, but he recovered without any medical help. On this account I thought it possible the present attack might be due to malignant malaria. The temperature was 99.4°F. and the pulse rate was 110 per minute, heart beat 'tictac', lungs normal, and spleen and liver were not palpable.

Blood films were taken for microscopic examination and quinine bilhydrochloride, grains xv, was given intramuscularly. A few doses of alkaline mixture with sedatives and a dose of calomel were given at night; cold application to the head was advised.

I was informed in the night at about 11 p.m. that the symptoms were not so violent as before, only the temperature rose to 101°F. I did not interfere further during the night.

18th July.—The patient was almost in his normal senses and the temperature came down to 99°F. He had two clear motions but his urine was very scanty, his eyes were still closed, he spoke rationally and complained of severe headache. The blood showed a few malignant tertian malaria parasites and there was a large mononuclear leucocytosis of 15 per cent. I gave him another injection of quinine and alkaline mixture with saline was given for the day. He was kept on fluid diet.

19th July.—The patient had improved considerably, he could open his eyes and his temperature was normal. Sinton's method of treatment for malaria was followed; he had no further rise of temperature and he recovered completely.

I am grateful to the Civil Surgeon, Rangpur, for allowing me to publish this note and to Dr. K. C. Banerjee for helping me in the examination of the blood.

* (Note.—According to the most recent work it is recognized that multiple hydatids in the peritoneum practically always arise as secondary to an hepatic or splenic cyst that has ruptured into the peritoneal cavity, liberating the scolices, some of which develop into cysts in every way identical with primary cysts.—*Editor, I. M. G.*)

Indian Medical Gazette

DECEMBER

MALARIA, ATEBRIN, AND MENTAL DISTURBANCES

MANY doctors who have had extensive experience with atabrin in the treatment of malaria and have used it in thousands of cases have never seen any instances of psychoses occurring in their patients as a result of its administration; on the other hand, ever since atabrin was first introduced instances of the occurrence of mental excitability and mental derangement have from time to time been encountered and reported. No special notice was taken of these isolated cases until Dr. Neave Kingsbury collected reports from practitioners in Malaya and published a series of seven cases in the *Lancet* at the end of 1934. He referred also to other cases that had occurred and had been reported at medical meetings in Malaya. In the majority of the cases the mental disturbance was of short duration and in other instances the patients had previous personal or family histories of psychosis. The first symptoms appeared at different periods in the course of treatment and in no instance had the patients received more than a seven-day course of 0.3 gramme daily by mouth, but apparently all were receiving the full oral dose of 0.1 gramme three daily; Dr. Neave Kingsbury suggested that it might be advisable to sacrifice efficiency to safety and give not more than 0.2 gramme daily. Atabrin has been very extensively used in Malaya, so that these cases he reports are collected from probably tens of thousands of cases in which the drug has been given by the oral route.

Atabrin dihydrochloride had been administered by the intravenous and intramuscular route, both experimentally and clinically, before the highly-soluble compound atabrin musonate was introduced, but no large series of cases had been published. The special circumstances that were brought about by the malaria epidemic in Ceylon, combined with the dramatic results that were obtained with one or two large doses of atabrin musonate administered parenterally—reported in our April issue by Doctors Blazé and Simeons—have led to the extensive adoption of a plan of treatment of malaria that should possibly have been reserved for special circumstances.

In a paper included in our present issue and to which we shall refer again, Dr. Udalgama states that in Ceylon 'the standard form of treatment with this preparation (atabrin musonate), for an adult suffering from malaria, is two intramuscular injections each equal to 0.3 gramme of atabrin [presumably this means 0.375 gramme of the musonate which is

equivalent to 0.3 gramme of the dihydrochloride] with an interval of 24 hours between injections'. When this 'standard form of treatment' was applied under epidemic conditions in a mixed, probably ill-nourished population, one of the immediate results appears to have been an increase in the number of cases of psychosis. Incidents have occurred where the behaviour of the patients has brought them within the scope of the Law, reports have appeared in the public press, these ill-effects have been attributed to atabrin per se, and a false impression has been created.

In the paper referred to above, Dr. Udalgama reports seven cases of mental disturbance that occurred in a series of 644 cases treated with the 'standard' course of atabrin musonate. In five instances the maximum dosage was given; in one a child, aged 8, two doses of 0.16 gramme (atabrin equivalent) were given and in the other a single dose of 0.2 gramme. The duration of the psychoses was from 17 hours to over two months; in the last instance the later symptoms were ill-defined and from the history it seems possible that there was some other factor in the aetiology. In another instance, it would appear that the symptoms were such that it is doubtful if they should have been classed as primarily mental; the patient was admitted to hospital in a collapsed semi-conscious state and eventually died 'from mere exhaustion', a state of affairs more likely to be due to malarin than atabrin. As there seems to be some doubt if this last case should have been included in the series, we can place the incidence of mental symptoms at about one in every hundred cases treated.

In another paper in the present number, three Ceylon practitioners have summarized their experience based on the treatment of 3,500 cases in which they used the parenteral as well as the oral route for the administration of atabrin. They advocate smaller doses by intramuscular injection, 0.15 gramme atabrin hydrochloride or the equivalent in the form of the musonate, for an adult; they give two such doses and then complete the course of treatment by oral administration. In their experience mental excitability is rare and when it occurs is easily controlled by sedatives; they place the incidence of this mild form of mental disturbance at one in two hundred cases.

Cerebral excitation and more serious forms of psychosis have always been recognized as possible complications of severe malarial infections, and it is probable that instances of these conditions have been wrongly attributed to the action of atabrin. However, the evidence that we now have before us does seem to indicate that there is some aetiological connection between these mental disturbances and the administration of atabrin in a malarial subject, though there is as yet no evidence to suggest that they are the result of the action of atabrin

per se on the tissues. We know little about the mode of action of atabrin on malarial infection, but, whether the action is a lethal one on the parasite itself or a stimulative one on the tissues, it is quite conceivable that a sudden liberation of malarial 'toxins' or of the results of katabolic processes, following a large effective dose of atabrin, might produce cerebral symptoms. On the other hand, it is possible that a large, though normally a sub-toxic dose, of atabrin might produce direct toxic effects in persons with a specific sensitivity or whose tissues have been damaged by the malarial infection.

Whatever is the mode of action of this drug the evidence does seem to suggest that the frequency of the occurrence of mental symptoms bears direct relationship to the size of the dose of atabrin administered; when oral administration only was used, they were very rare; with a moderate parenteral dose (0.15 gramme), they are still comparatively rare and always easily controlled; and with the larger doses (0.3 gramme), the psychoses may occur more frequently and tend to be more serious and more prolonged. This observation does not lend any support to either theory regarding the causation of these mental disturbances; if the action is direct, it would be natural that the larger the dose of the drug the greater is the number of persons that are likely to be affected, or, if it is indirect, again the greater the dose the greater will be the amount of malarial 'toxin', or products of katabolism, liberated.

In any discussion on the toxicity of a drug there are two things to be considered, the drug and the individual to which it is given. If the drug is a stable chemical compound, the drug factor is probably a constant one; the individual factor is, however, never constant. If you take a large number of white mice, all bred from the same strain under the same conditions and all approximately of the same weight, divide them up into batches of ten, and give increasing doses of a toxic drug to each batch, you will not get a hard and fast line between the lethal and the sub-lethal dose of the drug. There may be a very considerable disparity between the dose that all the mice survive and the dose that kills them all, and it is not uncommon to find that some mice will survive even 10 times the dose that killed others. If this occurs in a comparatively homogeneous population, one must expect a greater range of susceptibility in man, in whom there are variations, not only in age—for this, allowance is usually made—but, in race, in weight, and in general state of health.

When a drug is first introduced into therapeutics the dosage that is used is necessarily arbitrary. Admittedly, it will have been based first on animal experiments and then on a few controlled experiments on man. A dosage that is considered to be well within safe limits is always chosen, but the individual factor is such

an uncertain one that subsequent experience may show that, though this dose produces no symptoms in the first 100 cases in which it is used, in the 101st case it will produce alarming symptoms, and the original dosage may have to be modified. This actually happened in the case of plasmochin; the original dosage suggested was undoubtedly too high, and safer doses are now recommended by the introducers of this useful drug. The dosage is, of course, also governed by the therapeutic considerations, as it would be absurd to give a drug, however harmless, in doses above the maximum effective dose, but even this can only be ascertained by extensive clinical trial.

It seems to us that in the case of atabrin the dosage first suggested was in all probability the optimum one. A five-day course of thrice-daily doses of 0.1 gramme seems to be a therapeutically effective one, to be a course not so prolonged that in ordinary circumstances the patient loses interest and fails to co-operate, and to be a dosage with a very considerable margin of safety, though, as we have seen, rarely untoward symptoms do occur. Future experience may show that a twice-daily dose extended over a period of seven days is almost equally efficacious, though the data we have at present do not indicate this.

On the other hand, experience does seem to have indicated that if the dosage is increased above this optimum the chance of untoward symptoms occurring is also increased. Circumstances may demand that this extra risk should be taken; for example, in severe types of malignant malaria, parenteral injections may be indicated, and in Ceylon, where mass treatment was carried out in villages, the large intramuscular injections were obviously justifiable on the grounds of administrative expediency.

To return from the general to the particular, we must face the fact that with the ordinary dosage of atabrin instances of temporary mental excitation will very rarely occur, and that if we increase the dose, as in certain circumstances it may be perfectly justifiable to do, we are increasing the chances of the occurrence of these mental symptoms and we must warn our patients accordingly.

PAUL EHRLICH AND THE SALVARSAN SILVER JUBILEE

THE treatment of syphilis by the organic arsenical compounds is such an established part of everyday practice that it is hard for the practitioner of the present generation to realize that only a quarter of a century ago the first reports of Paul Ehrlich's great discovery were being received with a combination of scepticism and enthusiasm by the essentially conservative medical profession. Both the enthusiasts and the sceptics will remember what they said—or some of what they said—and will no doubt consider that time has justified their optimism

—or pessimism, as the case may be. Admittedly, the *therapia magna sterilisans* that was expected to follow immediately on the heels of '606' has not matured, but few, even of the most enthusiastic, can have foreseen that in so short a time this new science of experimental chemotherapy, of which the preparation of salvarsan was the first striking success, would place within the reach of the physician so many new missiles to use in his fight against disease.

The physician in the tropics in particular owes much to chemotherapy as it has given him, as well as salvarsan itself which he uses in syphilis, yaws, relapsing fever and rat-bite fever, a number of specifics for conditions that were considered incurable only a few years ago, Bayer 205 and tryparsamide for the treatment of trypanosomiasis, stibanyl, urea stibamine and neostibosan for leishmaniasis, and antimosan and foudadin for schistosomiasis, and many other powerful drugs, such as carbarsone, atelrin, and plasmochin.

Paul Ehrlich, born in Silesia in Germany where the art of dyeing flourishes as an old

P Ehrlich

handicraft, was familiar from his boyhood with dyestuffs and the very knowledge that in technical processes certain dyes were fixed by certain fibres gave a strong impulse to his research work in later years, so that it was not a matter of pure chance that he took up this line of research.

As a research worker he combined accuracy and power of deduction with a plastic and vivid sense of imagination. When attending the microscopical courses as a young student in Strasburg, his one-time teacher Prof. Waldeyer found to his surprise Ehrlich's place in the laboratory covered by a patchwork of stains of many colours and asked the student what he was doing. The answer was: 'I am staining',

whereon his teacher could only reply 'Well go on by all means'.

Paul Ehrlich never abandoned his particular fondness for dyestuffs and their effect on dead and living tissues. He very soon became aware of the immense importance of this question for biochemical problems. His first work was a treatise on the differential staining of leucocytes. He proceeded further by studying the oxidation and reduction in the organism and the action of dyestuffs on trypanosomes and finally on spirochetes. Thus, he became the founder of modern chemotherapy proper which aims at destroying the parasites only without affecting the host organism. If one takes the trouble to go through his lecture on chemotherapeutic investigations delivered at the session of the German Dermatological Association (Frankfurt, 1908), it is a matter of surprise that the striking success of his trials with animals did not make a far greater impression on the medical profession than was actually the case. But even Ehrlich himself, influenced by his friend Neisser, was convinced of the curative effect of mercury as a specific in syphilis to such an extent that he only reluctantly entered a new path in the fight against this disease.

Ehrlich's work received a fresh impulse when Paul Uhlenhuth in 1907 demonstrated the striking effect of the arsenic preparation atoxyl in fowl spirochaetosis, an action which was confirmed in collaboration with E. Hoffmann in experimental syphilis in monkeys. Ehrlich found a willing helper in his chemical work in Berthelm and in his experimental work Hata took a considerable share, although all the time Ehrlich's mighty genius guided their work.

He tried 605 different compounds, each one of which failed to come up to the mark in some respect or other. At last the 606th preparation, chemically a dioxy-diamino-arsenobenzol-dihydrochloride, was synthesized and experiments on rabbits with this preparation gave such overwhelming results even with one injection that a trial in human beings suggested itself. Apparently a *therapia sterilisans magna* had been found which immediately destroyed *Spirochaeta pallida* without endangering the patient himself to an undue extent. Still, treatment with atoxyl and its potential dangers were yet fresh in the minds of the profession and it was not easy for Ehrlich to find anybody who would take the responsibility of carrying out clinical tests with this new powerful preparation. Professor Konrad Alt was the first to adopt Ehrlich's ideas and to introduce treatment with '606' in his clinics at Uchtspringe. Two of his assistants, Drs. Josef Hoppe and W. Wittneben whose names deserve to be told to posterity, tried the preparation on themselves and only when these injections were borne without serious by-effects were further trials carried out with 0.3 g. of salvarsan

reckoned with as a real menace in the life of the Assam ryot.

Kahn tests

Routine Kahn tests have given the following results :—

Number of sera tested	Number negative	Number positive
46	37	9

Epidemic diseases

In 1934, Assam was visited with a wide-spread epidemic of measles with an average mortality rate of 2.2 per cent mainly amongst children. Laboratory work here was directed to the preparation of 10-day convalescent serum which was administered to a large number of contacts with excellent results.

Serum was collected, tested by the Kahn method and for sterility, and released for use in the epidemic area. The results are recorded elsewhere (Manson, 1935). The total number of contacts treated with this convalescent serum was 285, of whom only 3 contracted measles subsequently.

Vaccines

Autogenous vaccines are now prepared for suitable cases and the following table shows the number and type of vaccines made from June 1934 to October 1935.

Number of autogenous vaccines prepared	Type of vaccine	Notes
12	<i>Staphylococcus aureus</i> , <i>citreus</i> and <i>albus</i> .	
4	<i>Streptococcus hæmolyticus</i> . <i>Staphylococcus aureus</i>	Mixed vaccine.
2	<i>Pneumococcus M. catarrhalis</i> <i>Staphylococcus aureus</i>	Mixed vaccine.
5	<i>B. coli communis</i>	
1	<i>B. pseudo-carolinus</i>	
1	<i>B. pseudo-asiaticus</i>	
25		

Stool examinations

In addition to the routine stool examinations for helminth infections, etc., laboratory facilities here have been added to enable stool cultures to be carried out at the source.

The following table shows the results of these examinations :—

Result of stool culture.—The number of stools examined between December 1934 and October 1935 were 187. Of these, 33 showed the presence of non-lactose fermenters and the distribution was as follows :—

Organism isolated	Number of each species	Percentages
<i>B. pseudo-carolinus</i> ..	5	15.16
<i>B. pseudo-asiaticus</i> ..	6	18.18
<i>B. lunavensis</i> ..	9	27.27
<i>B. para-asiaticus</i> ..	2	6.06
<i>S. paradysenteriae</i> ..	1	3.03
<i>Enterococcus</i> ..	6	18.18
<i>B. faecalis alkaligenes</i>	1	3.03
<i>B. enteritidis</i> (Gaertner)	1	3.03
<i>B. pyocyaneus</i> ..	1	3.03
<i>B. cloacæ</i> ..	1	3.03
TOTAL ..	33	3.03

The organisms found are of interest in that the *B. shiga* and *B. flexner* are not present. This cannot be taken as absolute as the number examined is too small to allow of definite conclusions regarding Assam infections in general.

The presence of *B. pseudo-carolinus* and *B. pseudo-asiaticus* and similar organisms is of considerable importance, as these, which are possibly phage-modified types, are predominant in this small series. A comparison with the table on page 40 of the Annual Report of the Calcutta School of Tropical Medicine is instructive, as it shows the same paucity of Shiga and Flexner infections.

Negative results in stool cultures made from old stools are extremely uncertain as rapid overgrowth of secondary organisms occurs and may entirely swamp the original infection. This point emphasizes the need of field laboratory work, not only here, but under all similar conditions.

Urine examinations

The number of urine samples sent for culture was 19. Of these 12 were negative and 7 showed the presence of *B. coli communis*.

Conclusions

In compiling these notes, I am fully aware that I am adding nothing to the general knowledge of laboratory findings. They are mainly recorded to show what lines of laboratory work may conveniently be undertaken in a small field

laboratory and to emphasize the assistance that can be given on the spot to clinical work in coolie hospitals.

No plethora of apparatus is required. Beyond decent microscopes for blood work and dissection, a suitable incubator (preferably electric), a centrifuge, the usual laboratory glassware, culture media, etc., little is required.

A certain amount of application on the part of the medical officer is necessary to overcome the *vis inertiae* which is so characteristic of Assam conditions.

The benefits to the community are immediate and striking both in the reduction of sick rates and in reduction of medical expenditure. I have mentioned only the salient features of field laboratory work here and have not enumerated this paper with records of subsidiary biochemical laboratory work which lies beyond the sphere of tea garden requirements.

If I have roused the interest of my medical confreres, I shall feel that this short paper has not been written in vain.

Acknowledgments

I am indebted to the Calcutta School of Tropical Medicine for much help especially to Dr. L. E. Napier and his assistants, Dr. C. R. Das Gupta and Dr. Dharmendra. Also in the first instance I am indebted to the Ross Institute for help in carrying out anopheline survey work and in assisting the laboratory financially. Finally thanks are due to my chief laboratory assistant, Dr. L. R. Dey.

DRUG ADULTERATION AND SPURIOUS DRUGS IN INDIA*

By R. N. CHOPRA, C.I.E., M.A., M.D. (Cantab.)
M.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pharmacology, Calcutta School of Tropical Medicine

Introduction.—That the market in India was being flooded with drugs and chemicals of defective strength and impure quality by unscrupulous traders and that potent remedies, such as sera and vaccines, were being freely sold to the public without their quality being tested, was pointed out in the Council of State as early as 1927 by the Hon'ble Sir Haroon Jaffar. He characterized the practice as a great menace to the public health and called for the prompt

institution of efficient safeguards to ensure the quality and authenticity of medicinal preparations offered for sale to the public. The discussion that followed showed an appalling state of affairs and the Council recommended to the Government of India to urge all Provincial Governments to take such steps as may be necessary to control this state of affairs. In the Legislative Assembly Col. Sir Henry Gidney stressed the fact that India was *par excellence* the dumping ground for every variety of quack medicine and adulterated drugs manufactured in all parts of the world and that her markets were glutted with useless and deleterious drugs sold by unqualified chemists, who were themselves a public danger. He pleaded strongly for the immediate introduction of effective legislation to eradicate the existing evil. The commercial community were also alive to the fact that a large number of chemists and druggists stocked drugs of inferior quality for sale and that this had adversely affected the pharmaceutical industry in the country. Public opinion expressed itself in no uncertain terms and medical and scientific journals took up the question. The *Indian Medical Gazette* described India as a land of quacks, quack traders and quack medicines. The leading newspapers, such as the *Statesman*, vigorously championed the need for legislative interference to protect the masses from the perils of the situation. In response to this volume of opinion, the Government of India appointed a small *ad hoc* committee to explore and define the scope of the problem with reference to actualities and to make recommendations. Of this committee I was appointed the chairman and I therefore had the opportunity of coming intimately in contact with the problem as it existed all over India. The committee started work in October 1930, toured all over India and received a large mass of varied and voluminous evidence, both written and oral. It heard a wide range of opinion on both the medical and the commercial sides of the problem. All aspects of the question were carefully and systematically considered. The committee found that the situation as described in the Council of State and the Legislative Assembly was not in the least bit exaggerated; in fact it was even worse and called for stringent measures to cope with it. It is nearly four years since the committee completed its labours and made its report. On account of financial stringency it has not been possible for any action to be taken and the position has not improved. It would in fact appear from various reports that have been published in the press from time to time in different provinces that things have gone from bad to worse. In Bombay spurious drugs with counterfeit labels having the names of well known firms have been seized recently (February 1935), and the Committee of the Bombay Chemists and Druggists Association has passed and forwarded to the Government a resolution

* Being a paper read before the Calcutta Rotary Club on 5th November.

of apprehension and great alarm on the ever-increasing menace of adulteration of drugs prevalent in the country and of the frauds committed on the general public by unscrupulous dealers and fakers, to the detriment of the health of the public. A similar resolution reached the Government of India from an important body in the United Provinces last August and there is no doubt that the situation all over the country is the same. I can say from personal knowledge of Calcutta, which is one of the biggest drug trading and manufacturing centres in India, that the state of affairs is chaotic in the extreme, and manufacturers of standard products are suffering heavy losses. I will now tell you briefly how different classes of drugs are effected.

The quality of drugs and chemicals on the market in India

Firstly, I will explain the extent to which the drugs and chemicals of the British Pharmacopœia which are of impure quality or of defective strength are imported, manufactured or sold in India. This is the central problem as this group of drugs is the largest in use. There is unfortunately no room for doubt that in regard to adulteration, deterioration or tampering with the quality and strength of drugs very little distinction could be made between imported and locally manufactured medicinal preparations. It is well known that firms abroad manufacture drugs specially for the Indian market and, in the absence of control on the quality of drugs manufactured for export, these countries are able to undersell the local manufacturer of drugs. The dumping of inferior quality of drugs has its repercussion on the quality of drugs manufactured in India in that the quality is deteriorated to keep pace with the competitive rates of the dumped goods. A class of manufacturers has thus arisen who make and sell inferior and sometimes absolutely inactive products. Having regard to the seriousness and far-reaching character of the problem, the Drugs Enquiry Committee collected a large number of samples at random from different provinces and I subjected them to a careful analysis in my own laboratory. It was definitely proved that not only was adulteration common, but many firms sell packages which are considerably under strength and underweight. A perusal of the report of the committee will show what a large number of preparations are involved. The medicinal preparations were found considerably below strength and instances were met where quinine was entirely omitted from quinine tablets.

This state of affairs is in no way altered since and there is no doubt whatever that many of the drugs on the Indian market at the present time are of impure quality and defective strength. I can say from personal knowledge

that the traffic in such drugs at the present time is extensive and indiscriminate and the statements which have recently appeared in the press are in no way undeserved and exaggerated.

The second large group of drugs are those which are not officially recognized by the British Pharmacopœia but are known and approved medicines and are largely used. The extent to which such drugs of impure quality and insufficient strength are indiscriminately manufactured, sold or imported is the same as that of the pharmacopœial drugs. The groups of biological products include sera, vaccines, preparations from animal glands, hormones, etc., besides these there are complicated organo-metallic compounds containing arsenic, antimony, etc. Those imported into the country are frequently made by reliable firms of manufacturers having established reputations. The climatic conditions and defective storage, however, may produce rapid deterioration in their potency and it is well known that many of the retail sellers have not proper arrangements for storage of these products. Some of the importers do not hesitate to descend to the vile practice of getting hold of time-expired biological products from the European markets, importing them into India, and selling them to the dealers at a very cheap rate.

As regards those manufactured in this country, very few of the firms in India have the personnel and equipment to produce these products and therefore many of the preparations are not up to standard. Unfortunately complicated compounds of arsenic and antimony can be manufactured in India by anyone who may choose to do so and these potent compounds are being actually put on the market without their toxicity and strength being properly tested. Their standardization is at present left entirely to private enterprise and to manufacturers, and each maker is free to adopt his own conception of adequate standardization; there is no check whatever by the State. In other countries the toxicity of each batch of such complicated and potent preparations has to be carefully tested before they are allowed to be sold to the public. No licence is granted to any firm until the licensing authority is satisfied that the personnel and equipment of the firm is qualitatively and quantitatively efficient for the purposes for which licence is sought. In addition to this licensing system, samples of finished products are tested by the laboratories under State control. While in other countries careful watch is kept over these potent compounds the Indian public is entirely unprotected. The position indeed is discreditable to the country and is a source of great danger to the public. I have recently tested some of these compounds whose toxicity is high and yet they are being sold to the public, one shudders to think with what consequences.

The third group of drugs we are concerned with are the patent and proprietary medicines. The Indian market is inundated with proprietary and secret medicines both imported and of Indian origin, and their sale is increasing by leaps and bounds. The public in India consume them voraciously on account of the ingenious propaganda, and clever and alluring advertisements of their supposed virtues. The credulity and gullibility of the masses, especially when 'certain cures' are assured in utterly hopeless cases, can well be imagined. Perusal of advertisements of 'cures' produces a great effect on the patients who have tried treatment by medical men without success. The promise of cure, the force of argument advanced to guarantee it and the certificates of persons said to have been cured (who often do not exist at all) which are all set out in the advertisements make a deep impression. There is no doubt that while there are useful preparations among these, there are also positively injurious and fraudulent combinations and, on account of the lack of any State control in this country, their number is quite large.

What are the results of drug adulteration?

The substitution of genuine medicinal products by rubbish has now reached a very serious stage and its results can be easily imagined. In the case of pharmacopoeial drugs the patients to whom these drugs are prescribed will naturally not benefit by them. In diseases such as pneumonia, diphtheria, etc., it may make all the difference to the life of the patient whether he is getting a drug of proper strength or an adulterated or useless preparation. In the case of complicated organo-metallic compounds if they are not properly prepared and tested and in a state of absolute purity, their use will be positively dangerous and fatalities may occur. In the case of biological products, incalculable harm may follow the use of products which are improperly prepared or stored. The injection of faked insulin in cases of diabetic coma may lead to the death of the patient. The Medical Research Council in England have described the absence of control over these products as 'a source of grave danger to the country'. The misery, breakdown in health and mortality that might follow the use of some of the patent, proprietary and secret medicines cannot possibly be overestimated. Much harm may result from the use of such medicines in negative as well as in positive ways. A patent medicine might be injurious and cause direct harm as some of the constituents may be positively dangerous in absence of control. Some medicines might have the effect of masking early symptoms of serious and grave diseases and, assuaging them for a short period, result in delaying scientific diagnosis and treatment. Much valuable time may thus be wasted and investigation delayed until it is too late to do anything. It is for this

reason that rigid control is exercised in many countries over extravagant claims made in advertisements and that the law prohibits statements which are untrue, deceptive or misleading.

The remedy

How can the present unsatisfactory position be remedied? The Drugs Enquiry Committee has gone very carefully into the whole question and worked out a scheme by which control can be exercised on the medicinal preparations. This scheme has been generally accepted as being sound and effective. The essential parts of the scheme are firstly legislation and secondly machinery to collect and test drugs.

So far as the existing legislation is concerned, there is no enactment in the Indian legislature which aims directly at the prevention of adulteration or which ensures conformity to proper standards of purity and strength. Certain sections in the Indian Penal Code, the Indian Merchandise Marks Act (1889) and the Sea Custom contain some provisions bearing on it, but in actual practice they are difficult of application. The result is that mere adulteration of drugs is not, by itself, prohibited in British India by enactment. Nor is the sale of a drug of insufficient strength or improper standard punishable except on the basis of 'misrepresentation' and 'fraud'. These expressions are vague and are of inconclusive import. The baneful results of adulteration or defective strength of drugs may be slow and gradual in making themselves evident. The non-existence of fixed standards or methods of analysis, the absence of any precise definition of adulteration, the want of skilled experts and of well-equipped laboratories, the difficulty of proof and the fact that intention or knowledge is the essence of these offences, as well as cheating, complicate the situation and render the provisions ineffective in actual practice. The Calcutta Municipal Act of 1923 and Bengal Municipal Act of 1932 deal with foods and drugs in a fairly comprehensive manner; the former defines the expressions 'adulterated' and 'misbranded' in relation to foods and drugs, but unfortunately there is no machinery to work these. Most of the other provinces have some sort of legislation. For proper control of drugs, however, there should be central legislation for the country as a whole, because that is the only way in which effectiveness and uniformity of control throughout India can be brought about. This part of the scheme does not need any monetary expenditure and could be proceeded with at once.

The machinery to test medicinal preparations consists of a well-equipped central laboratory with a competent staff of experts in various branches, as well as provincial laboratories working under the guidance of the central laboratory. The provision for control includes the appointment of inspectors, who will be

appointed by local governments to pick up specimens and send them to the provincial laboratories for testing. It will thus be seen that, in any scheme of control, the Central Government as well as the Provincial Governments must take part. This portion of the scheme is bound to cost money in the beginning though later on a good deal of revenue will be obtained. On account of financial stringency funds have not been forthcoming, with the result that we are now in the same position as regards the control of drugs as we ever were.

In all fairness to the Central and Provincial Governments it may be said that the problem in India is not so simple as it looks. The profession of pharmacy is still unorganized in India and the question of the purity of drugs and the profession of pharmacy are interdependent. The important part which the pharmacists play in relation to drugs needs no special emphasis. They are the custodians of drugs. They prepare, compound and sell them, and on their efficiency depends the purity of the drugs dealt with by them. To ensure efficiency in discharge of duties and to guarantee that the drugs and medicines compounded, prepared, dispensed or sold are of proper strength and quality, it is essential that the pharmacists should be properly trained and under control. An untrained person cannot appreciate the value of scrupulous accuracy and the importance of purity and strength of medicinal preparations. In most parts of India at present anybody can compound and sell medicines. My committee worked out a scheme for organization of the profession and for the proper training and registration of those who practise it as a part of drug control. This is the only thing which will make them realize their responsibility, and thus help towards the disappearance of adulterated and spurious drugs.

Another problem which complicates matters in this country is the practice of the Indian systems of medicine and the drugs used by them. A very large proportion of the population, particularly in the villages and small towns, resorts to the indigenous systems of treatment and there is no doubt that many of the crude drugs as well as the compounded medicines offered for sale to the public are adulterated and of poor quality. Many of the practitioners in these systems use potent and toxic substances over which control is absolutely essential. It has been urged that if any legislation is undertaken for ensuring the purity of drugs, it should not be confined to drugs used by a small section of the population, namely those resorting to the western system of treatment only, and one may be disposed to argue that legislation which aims at dealing with the drugs used by the western system only will be truncated and lack in completeness of perfection. In the absence of standards, however, these drugs cannot be treated on the same lines

as drugs and chemicals recognized by the British Pharmacopœia and other western preparations. The only possible way is to keep the drugs and preparations of the indigenous systems separate at present. Yet another difficulty is the existence of foreign territories and Indian States in close proximity to the provinces.

Such is the problem of adulteration of drugs and its control with which we are faced in this country. The problem is undoubtedly a difficult one, but a remedy must be found to rectify the present state of affairs. Although public health is essentially a provincial subject, foods and drugs have not attracted the attention of local legislators to the extent they deserve. Drugs have fared worse than foods in this respect. I have already emphasized that no system of control in which the Provincial Governments do not take their due share along with the Central Government will be workable. Both must do their bit. An editorial in the *Statesman* recently under the title of 'Keeping a nation fit' reviewed the report of the British Ministry of Health of which the control of drugs forms a very important part. It pointed out that expenditure on public health is a long-term investment and that purity of food and drugs is the first line of attack in the unceasing war against disease and epidemics. Those who have the control of the purse in this country should follow the lead given by Britain who has invested large sums of money on public health matters and is already receiving the dividend on the long-term investment. Indian statesmen will we hope view this problem with the same breadth of vision as statesmen in other civilized countries have done.

THE COMBINED SYSTEM OF SOIL, WATER AND VENTILATION PIPES

By H. G. D. MATHUR, B.Sc., M.B., B.S., D.T.M. & H.
M.R.C.P.E., D.P.H.

Professor of State Medicine, Lucknow University

THE standard English practice for the water-carriage system has always been the provision of pipes for household waste water separate from the soil pipes, the latter receiving the discharge from water-closets only, and the prolongation upwards of both the waste-water and soil pipes as ventilating pipes, the necessary anti-siphonage pipes being provided where there are more than one story. This practice has also been followed in India. Practice in other European countries, as well as in America, has however been for a single pipe which received simultaneously the discharges from all toilet and kitchen fittings. Efforts are now being made to popularize and legalize this system in Great Britain and it has been labelled as the 'one pipe' system.

The London County Council undertook comprehensive changes in their drainage and sewerage by-laws in 1933 and within two years they published draft by-laws introducing radical changes in the requirements and adopting the 'one pipe' system. These by-laws are now in force and it is proposed here to describe in brief the main features of this system, how it differs from the old system and the advantages that are derived from it.

The following are the essential features of the new system (figure 1), as contrasted with the corresponding requirements of the old system (figure 2).

Fig. 1. New system.

1. All conveniences in a house—water-closets, baths, lavatory basins, kitchen sinks, etc.—are joined directly to the same pipe; formerly all fittings other than a water-closet were to be joined with a separate waste-water pipe and then through a gully trap to the soil pipe.

2. Formerly the water-closet had to be, either in a separate cubicle outside the house, or, if inside, it should adjoin an outside wall and the connecting pipe should pass out directly, the whole of the soil pipe being outside the building. Now the soil pipe need not be placed on an outside wall and may pass through inside a house, though a separate shaft open to the

sky for the soil pipe would be desirable. This permits the location of a water-closet practically anywhere in the house.

3. The ventilating pipe is also a single one beginning from the soil pipe below the lowest

Fig. 2. Old system.

sanitary fitting and all anti-siphonage pipes are joined to it, whereas formerly the ventilating pipes for the soil pipes had to be separate from those for waste-water pipes.

4. Deep seals. $2\frac{1}{2}$ to 3 inches are to be provided and every one of them is to have an anti-siphonage pipe except when special seals that resist unsealing are installed (figure 3). Formerly all traps had to be ventilated, even

Anti-vac Trap showing how it resists Unsealing

(Modified from "Specification" 1933.)

Fig. 3.

though there were no risks of their being unsealed through siphonage action.

5. As all fittings are now to be connected directly to the soil pipes, gully pits are not required except where rain water or surface wash water is to enter the sewerage system. Formerly all sullage-water fittings were to discharge in the open air outside into a channel leading to a trapped gully pit at least 18 inches distant from the discharge openings.

6. An intercepting chamber, or in small installations a disconnecting and ventilating trap, was obligatory for all. This is now considered not only redundant but even pernicious.

7. The soil pipes are to be of cast iron, discharge pipes from toilet fittings are to be of copper so that the presence of hot water in them may not introduce complications through expansion.

The main advantage of the 'one pipe' system is the considerable reduction in cost of installation through the reduced number of pipes and ventilating shafts, the abolition of gully traps and of the intercepting chambers.

For Indian towns this is a considerable advantage as it would place the water-carriage system within reach of the small householder who though cognizant of its advantages has to deny himself its benefit through considerations of cost alone.

The external appearance of a building would be considerably improved through the pipes being located inside it, or even if they are placed outside, through their numbers being considerably decreased.

A gully trap, even when properly designed, catches a small quantity of the suspended matter which putrefies and, inasmuch as the water passing through gully traps (particularly under Indian conditions of a more concentrated sewage) may be charged with considerable amount of organic matter, much nuisance is produced through the interposition of several gully pits with traps. Abolition of such traps would lead to considerable abatement of the nuisance from this source.

On the other hand, no harmful effects have been noticed as arising from this system in any of the countries where it has been in use. The old recommendations date back to the pre-bacteriology era when sewer gases and effluvia from polluted soil and decomposing organic material were considered potent factors in determining the causation of zymotic diseases in general and typhoid fever and diphtheria in particular. Modern bacteriology has dispelled all that vague belief and replaced it by the definite knowledge that sewer gas is harmless in itself and may even be better than the atmosphere of some of the dirtier streets.

Thus, as the 'one pipe' system has been successfully used in so many countries and as it has been adopted in England, it is considered desirable that it should be introduced in Indian towns which have sewerage systems. This would enable the middle-class people to benefit more and more from sanitary facilities, thus brought within their reach.

It is very necessary that for Indian conditions a set of minimum standard requirements in sanitary engineering, including plumbing, be laid down similar to those laid down recently in Great Britain by the Institute of Plumbers, or some time back (1924) in the United States of America by a special sub-committee appointed by the Government Bureau of Standards. The report of the latter sub-committee not only gives the standards but also all the experimental data on which they have been based.

Medical News

BOMBAY MEDICAL COUNCIL

THE following extracts from the summary of the proceedings of the meeting of the Bombay Medical Council held on 3rd September, 1935, are published for information:—

The Council proceeded to consider the application of the Rangoon University for the acceptance of the L.M. & S. of that university for registration under the Bombay Medical Act, 1912, and decided that Government be asked to add the L.M. & S. of the Rangoon University to paragraph 1 of the schedule to the Bombay Medical Act.

The Council proceeded to consider the application from the Director, Medical and Sanitation Department, H. E. H. the Nizam's Dominions, for the acceptance of the M.B., B.S. degree and the L.M. & S. diploma of the Osmania University, Hyderabad, Deccan, for

registration under the Bombay Medical Act, 1912, and resolved that the matter be referred back to the executive committee of the Council for further consideration in the light of the information since received from the Director, viz, that the medium of instruction at the Osmania Medical College, according to the regulations of the Osmania University, is Urdu.

The Council proceeded to consider certain papers received from Government relating to the question of recognition, for registration under the Bombay Medical Act, of the medical graduates of American "A"-class universities on certain conditions, which had previously been under discussion, and it was decided that, in view of the recent establishment of the Medical Council of India and the functions entrusted to it, it should be suggested to Government that the question be referred to that Council.

The Council considered the reports on the first L.C.P.S. examination received from the visitors appointed by the Council to attend and be present at the professional examinations for the L.C.P.S. and it was decided that the reports be referred to the College of Physicians and Surgeons of Bombay for the necessary further action.

The Council proceeded to consider an appeal from Mr. U. H. Sadarangani, M.A., B.S., of Karachi, regarding a resolution of the executive committee of the Council, laying down that the size of his signboards be reduced to the minimum and that, at the least, a 4-foot board be substituted for the existing 8-foot board, and it was decided to accept the resolution of the Committee.

The Council proceeded to consider the papers received from Government relating to the application of Mr. K. P. Deshpande for permission to be registered under section 7(2) of the Bombay Medical Act, 1912, and decided that, in the opinion of the Council, Mr. Deshpande may be given the permission applied for.

The Council proceeded to consider the question of the instructions to be issued to the visitors appointed by the Council to attend and be present at professional examinations and it was decided that, as the last visits of the visitors to the professional examinations for the L.C.P.S., Bombay, had only recently been completed, a further inspection of them this year is not necessary.

The Council resumed consideration of the application made by Mr. S. P. Lulla, M.A., B.S., for the restoration of his name to the Bombay Medical Register and resolved that his name be restored to the Register as a special case.

The Council proceeded to consider again the application of Mr. Motiram Tirithdas Ramchandani, M.A., B.S., for the restoration of his name to the Bombay Medical Register and resolved that some more time should elapse before Mr. Ramchandani's application is entertained.

The Council proceeded to consider the application of Mr. Narayan Krishna Paise, L.C.P.S., for the restoration of his name to the Bombay Medical Register and resolved that, in view of the short time that has elapsed since the removal of his name from the Register, his application for the restoration of his name to the Register should not be entertained yet.

The Council proceeded to consider the application of Mr. Ganpat Subrao Kasyapi, L.M. & S., for the restoration of his name to the Bombay Medical Register and resolved that, in view of the short time that has elapsed since the removal of his name from the Register, his application for the restoration of his name to the Register should not be entertained yet.

The Council considered a motion made by Mr. M. N. Talati, L.C.P.S., (1) that, in the absence of the benefits of a provident fund, the staff of the Bombay Medical Council be given a reasonable amount of bonus for the financial year 1934-35, and (2) that steps should be taken at a very early date to establish a provident fund for the benefit of the staff of the Council with effect from 1st April, 1935, and it was resolved that only the proposal to institute a provident fund for the staff be accepted and that the necessary further steps to work out the details be taken.

The Council proceeded to consider a motion made by Mr. R. A. Amesur for the creation of a separate cadre of teachers for the three government medical schools in the Presidency and for the proper equipment of the laboratories and museums provided for them and eventually it was decided to invite the attention of Government to the reports of the visitors appointed last year to visit the examinations for the L.C.P.S. and to the necessity for the introduction of a special teaching cadre and better equipped laboratories and museums for certain departments of the medical schools.

THE SETH GORDHANDAS SUNDERDAS MEDICAL COLLEGE MAGAZINE

We are pleased to accord a welcome to volume I, no. 1, of the *Seth Gordhandas Sunderdas Medical College Magazine*. It is very well produced and is printed on first class paper and it has an attractive cover on which are displayed the colours green, silver and purple, presumably the college colours.

The major portion of the ninety pages the number contains is devoted to short articles on medicine and surgery contributed by the student's teachers, but there are a few pages devoted to news and sport; these are placed near the middle of the book, between technical articles. We would suggest they might be better either at the end or the beginning.

On the whole it is a production of which the students of the college should be proud, and we congratulate them on their enterprise in commencing this magazine which cannot fail to be of social and educational value to them.

THE SOCIETY FOR THE STUDY AND PROMOTION OF FAMILY HYGIENE INCLUDING SEX HYGIENE

AIMS AND OBJECTS

The aim of the Society is, broadly, to help in increasing happiness in the marital and family relationships, and ensuring a general improvement of the human race. The family is here the central agent.

The institution of marriage is the basis of the family and sex is the most important factor contributing to harmony and happiness in marriage. While people have correct and even scientific knowledge of at least some aspects of family and marriage, their ideas about sex are often vague, misleading and even harmful. They are however becoming aware that there is a growing contrast between tradition and law regarding sexual life on the one hand and the real behaviour of men and women on the other. In consequence personal decisions on these matters have become increasingly difficult for the last two generations. Advice of every kind, psychological, medical, social, legal, and so on, is therefore more important to-day than ever before.

The value of all advice on sexual life depends wholly on scientific research. In view of the complicated aspects of sexology and its relations to other sciences, research cannot be of a medical nature alone but should be as wide and varied as possible.

The Society must therefore have its scientific aspect in the form of facilities for research as well as a practical one as an advisory centre on all problems coming within its scope. These can only be achieved by:

1. Granting scholarships and endowments for stimulating and organizing research on the subjects covered by the term, family hygiene.
2. Publishing reports, leaflets, etc., and also the quarterly *Marriage Hygiene* which will contain scientific contributions dealing with family, marriage and sex functions in their social and biological aspects.
3. Organizing propaganda for the introduction of sex education in all primary and secondary schools.
4. Starting and promoting family and marriage hygiene consultation centres and contraceptive clinics and co-ordinating the activities of those already existing.
5. Holding periodical conferences and arranging for lectures.
6. Supplying the best available advice to the members of the Society on their personal problems coming under the term family and marriage hygiene, such as, venereal diseases, legal difficulties, sex psychology, sex economics, etc.
7. Making available to members a library containing selected scientific books published on these subjects.

8. Collecting and collating manuscripts, press cuttings, photographs, etc.

9. Building up a museum for educational purposes.

10. Arranging to offer expert scientific advice in criminal sex cases.

The work is facilitated as the journal *Marriage Hygiene* has already international connections. The help and co-operation of experts have already been promised. In course of time, it is expected that the Society will either expand into an international organization or be affiliated to those working on similar lines in other countries.

Membership is open to adults of both sexes who are in sympathy with the objects of the Society. The subscription will be at the rate of Rs. 10 per annum; this will entitle the member to certain privileges and he will also receive the quarterly publication *Marriage Hygiene*. The present subscribers to this quarterly can join the Society by applying to the Secretary, and without further payment.

There are other classes of membership. Further details can be ascertained from the Secretary, who is also the Editor of *Marriage Hygiene*, Kodak House, Hornby Road, Bombay.

THE BOMBAY OBSTETRIC AND GYNÆCOLOGICAL SOCIETY

RESOLUTIONS adopted by the Bombay Obstetric and Gynæcological Society at its Meeting of the 27th August, 1935:

1. The Bombay Obstetric and Gynæcological Society believes that the recommendations made by the Medical Council of India in respect of the training of students in midwifery, gynæcology and infant hygiene are defective and inadequate, inasmuch as the prescribed period of three months for practical work in midwifery and gynæcology and fixing the minimum number of labour cases to be conducted by the student to five are not at all sufficient to give the student enough knowledge on the subject, as a general practitioner is expected to possess.

2. The society is of the opinion—

(a) That the period of practical instruction in midwifery and gynæcology should extend over a period of six months, instead of three as recommended by the Medical Council of India.

(b) That the minimum number of labour cases conducted personally by the student under adequate

supervision in a recognized maternity hospital should be fixed to twenty instead of five, as prescribed by the Medical Council of India.

(c) That it will not be practicable to conduct clinical examinations in gynæcology.

3. This meeting requests the honorary secretaries of the society that copies of the resolutions passed at this meeting should be sent to the following:—

(1) Medical Council of India.

(2) University of Bombay.

(3) The Bombay representatives on the Medical Council of India.

(4) Other Universities of India.

[Note.—We are in complete agreement with resolutions 1 and 2(a).]

With reference to resolution 2(b), we agree that the number should be 20 instead of 5, but there seems to be no necessity to lay it down so emphatically that the cases must be conducted in hospital. Despite the increasing tendency to institutionalization of midwifery cases, the major part of the confinements in India take place at home and will continue to occur there for many years. In the interests of the students, no less than for the improvement of domiciliary midwifery practice, we think practical experience of midwifery in the home would be a very valuable addition to the present training of the medical student. Facilities rarely exist at present for providing district experience under adequate supervision, and while it would seem preferable to make five cases in the district compulsory, the present situation could be best met by omitting the words 'in a recognized maternity hospital' from the resolution.

With reference to resolution 2(c), a final clinical examination in gynæcology was conducted in Scotland until quite recently and so far as we know is still a recognized part of the final examination. A clinical examination is certainly not impracticable in Great Britain and though difficult in India, it is not in our opinion impracticable. The estimate of the students' skill in gynæcological diagnosis need not necessarily be made during the course of the final examinations; the examination could be conducted at some prior date and a certificate of fitness given by internal and external examiners. We consider that some such practice is essential to ensure that reasonable facilities for acquiring experience are provided for the students and for rescuing gynæcology from the hands of half-trained nurses and *dais*.—EDITOR, *I. M. G.*

Current Topics

The Treatment of Acute Otitis Media

By F. H. DIGGLE, F.R.C.S.

(From the *Medical Press and Circular*, Vol. CXC.
26th June, 1935, p. 595)

ANY acute inflammation of the middle ear may be catarrhal or suppurative, and the latter may have a catarrhal stage, or be suppurative from the outset. The type of inflammation is determined by the nature and virulence of the invading organism, as well as by the patient's natural resistance. So far as the principles of treatment are concerned, the exact recognition of the type of inflammation is perhaps a matter of little importance. Suffice it to say that in the catarrhal stage the deafness is usually not so profound, the pyrexia not so high, and the congestion of the tympanic membrane more localized to the periphery and along the handle of the malleus. Both types can, therefore, from the point of view of treatment, be considered together.

Treatment

In the vast majority of instances the otitic inflammation is due to a spread of infection up the Eustachian

tube, following the common cold, influenza or one of the exanthemata. Quite commonly treatment directed to this common source of infection is neglected in a case which otherwise may be soundly treated. Treatment must, therefore, be directed to (1) the source of infection, (2) the otitic inflammation.

(1) *The source of infection*.—Hot steam inhalations, medicated with menthol, or, if a more antiseptic effect is desired, with menthol and iodine, should be given three or four times a day, according to the severity of the symptoms. A pint of hot water at a temperature of 140°F. is placed in a jug, and a few crystals of menthol or other medicant added. The patient is instructed to inhale alternately through the mouth and through the nose, and exhale through the nose and mouth respectively, with the head over the jug and a towel over the head. The following solution is particularly useful in the more severe pyogenic infection of the nasopharynx:

R. Mentholis	gr. v
Tincturis iodidi	} āā oz. ½
Acetici etheris			

Nasal douches and vigorous nose-blowing should be avoided, since both are liable to disseminate further infection along the Eustachian tube. For the same reason self-inflation of the ears, or politization, for the relief of deafness should be strictly avoided during the acute stage of the infection. The nasal passages may be gently cleansed by blowing down first one unoccluded nostril and then the other, at frequent intervals. On no account should both nostrils be compressed with the fingers over a handkerchief, as is the common practice.

If the nasal secretion be particularly profuse, the skin of the anterior nares may be protected by smearing with a little pure vaseline and an absorbent strip of gauze and wool and laid across the nostrils and secured by tapes behind the ears.

Inhalations may be supplemented or, especially in the case of very young children, replaced by instillation through the anterior nares of a few drops of Collosol Argentum (Crookes), or 2 to 5 per cent protargol twice daily.

Treatment of the middle-ear inflammation involves (1) absolute surgical cleanliness, (2) the relief of pain, and (3) the provision of drainage.

(1) *Surgical cleanliness.*—I am confident that if more attention were paid to this detail in the treatment of an acute otitis media the results would be greatly improved. An acute otitis media is primarily due to the invasion by a single organism, whether this be the streptococcus, the pneumococcus or the influenza bacillus, and any secondary infection of the middle-ear exudate from the lack of cleanliness undoubtedly tends towards chronicity of discharge.

So soon as a patient complains of earache, the external canal should be inspected and cleansed of ceruminous and epithelial debris by gentle syringing, and the canal sterilized by either syringing gently with a mild antiseptic lotion, such as carbolic lotion (1 in 60) or by the instillation of a few drops daily of 2 per cent carbolic acid in glycerine. The auricle should be cleansed with ether and spirit, and a sterile gauze dressing applied. I venture to suggest that if the ear were thus prepared at the outset in those exanthematic liable to acute otitis media as a complication, the results would be improved.

(2) *Relief of pain.*—It is always a matter of uncertainty whether anodyne drugs applied to the outer surface of an intact drumhead can, or do, relieve pain due to the accumulation and tension of fluid in the middle-ear cavity. Certainly drops containing cocaine or opium or its derivatives have very little, if any, effect. In the early stages a few drops of 2 per cent carbolic acid in glycerine do certainly afford some relief, and the application of dry heat to the ear, as by a lightly-filled hot-water bottle or a hot bran bag, is comforting. The pain of a middle-ear inflammation is mainly due to tension from the pressure of an inflammatory exudate in a confined bony space. As, therefore, the fluid in the middle ear increases, so does the pain, particularly if the texture of the tympanic membrane is such as to resist bulging and early spontaneous perforation. Too much time, therefore, should not be wasted in attempting to relieve pain by means other than the provision of free drainage to the middle-ear exudate.

(3) *Drainage of the middle ear.*—The early and free drainage of the middle-ear exudate afforded by an incision of the membrane—a paracentesis tympani—ensures in almost every case prompt relief to pain and undoubtedly greatly assists towards complete resolution of the middle-ear inflammation, with perfect recovery of hearing. In some few cases, notably severe streptococcal and influenza infections, pain is not immediately relieved by a paracentesis, but such is the exception rather than the rule. Then, again, one is frequently asked the question: 'Will this operation prevent a mastoid?' Admittedly, many 'acute ears', in which the membrane is allowed to perforate spontaneously make a perfect recovery. The size, situation and

incidence in the course of the inflammation of such spontaneous perforations are determining factors. Usually the spontaneous perforation is either too small or ill-placed to give free and dependent drainage; or else, owing to the structural density of the membrane, it occurs too late, after days of unnecessary suffering, to prevent serious infection of the mastoid process. I think, therefore, one can say with confidence that a timely paracentesis tympani does in the vast majority of cases prevent a mastoiditis. In some few, however, the infection is so virulent from the outset that the mucosa lining the whole middle-ear cleft, including the mastoid antrum, is grossly involved, and in these, in spite of an early paracentesis, a residual mastoid abscess is not avoided. Such types seem to run in epidemics, in which evidences of a severe generalized sepsis are predominant, and yet even in such one should not withhold at least an early skilled paracentesis.

The severity of the earache, the degree of bulging and congestion of the tympanic membrane or the inadequacy of a spontaneous perforation should be our criteria for a paracentesis. Pain not relieved in twenty-four hours, particularly with a rising temperature, demands immediate incision.

Treatment of middle-ear discharge

In assessing the value of treatment by drops, etc., to an acutely discharging ear, one should not overlook the undoubted fact that recovery not infrequently occurs without any treatment. Much harm, I am convinced, can result from too zealous after-care especially in the early catarrhal stage. The repeated instillation of irritative or viscid solutions, constant mopping of the external canal, and especially syringing, not only tend to produce secondary infection unless done under strict aseptic conditions, but quite frequently induce an irritative swelling of the external canal, hindering drainage, whilst forceful syringing may even drive infection into the mastoid antrum.

Nature has given us in the external auditory canal a perfect drainage tube, which, in my opinion, should be treated with great respect. It is extremely doubtful whether a sufficient quantity of ear-drops to be of any value can percolate through an incision in the ear-drum into a middle ear already full of exudate during the acute profusely discharging stage. One would first need to aspirate the middle-ear contents before applying the drops. Indeed, this procedure is, I believe, practised by a few, but requires skilled attention, and is, in my opinion, unnecessary and may even be harmful. The principles underlying successful treatment are, in any view, free and dependent drainage under strict aseptic precautions. A sterile pad of gauze and wool should be applied over the auricle, which has been previously cleansed with spirit or ether, and the patient instructed to lie on the affected ear for as many hours in the day as possible. If necessary, the skin of the auricle can be protected by smearing with sterile paraffin, and the outer dressing changed as frequently as necessary. Many cases, particularly if catarrhal, make a perfect recovery under this treatment alone. Should, however, the discharge be especially purulent and viscid, a few drops of hydrogen peroxide (vols. 10) may be instilled and allowed to remain three to four minutes, and the canal can then be gently mopped with a pledget of sterile cotton-wool, say, two or three times a day, according to the amount of the discharge.

Spirit drops during the acute stage are contra-indicated, as they only tend to produce pain. By the tenth to fourteenth day, in an uncomplicated case, the discharge begins to diminish, becoming more mucoid; and the use then of a few warmed drops, such as the following:—

R	Acidj boric		
	Spiritus vini recti	1	.. gr. x
	Aquæ	1	.. āā oz. ½

instilled once daily and allowed to soak for ten minutes, greatly assists resolution, particularly if any granulations are seen to be present around the membrane,

Persistence of otorrhœa

In a large percentage of cases the otorrhœa in a case so treated gradually diminishes, and by the end of the second or third week the middle ear is dry. Complete recovery of hearing usually takes a further four to six weeks, and if by then some residual deafness remains, gentle politization or self-inflation of the middle ear is beneficial. In some few, however, the otorrhœa persists, or may even increase. The cause must be sought for in the nasopharynx, the nose, the tympanic membrane and the mastoid antrum. A pad of infected adenoids or an unsuspected nasal sinus infection may be responsible. It is often surprising how frequently an acute nasal sinusitis complicates an acute otorrhœa, the existence of which is overshadowed by the ear symptoms. Each requires its appropriate treatment, but it is at this stage that I would particularly advocate the removal of adenoids. At one time it was my practice to remove the adenoids when the paracentesis was performed, *i.e.*, during the acute phase. A few cases, however, in which the previously healthy ear became seriously infected and the nasopharyngeal infection aggravated, altered my technique, with, I consider, improved results. I now prefer to treat the nasopharyngeal infection conservatively on the lines already detailed, removing, if the otorrhœa persists, the adenoids in the third or fourth week, or even months later, if the otitic inflammation has followed a normal course.

Occasionally the incision in the drumhead tends to close before complete cessation of discharge, or it may be blocked by granulation tissue. A second paracentesis, or the application of chromic acid with the daily use of spirit drops (75 to 100 per cent) is indicated.

Lastly, the course of continued otorrhœa may be, and usually is, due to infection of the mastoid antrum. How can such an infection be recognized? To await the classical textbook description of mastoid infection, namely, mastoid pain, tenderness and swelling, with displacement of the auricle, is a mistake. Valuable time can thus be lost in securing early cessation of discharge. The longer suppuration is allowed to persist, the greater are the risks of some degree of permanent deafness or tinnitus due to post-suppurative cicatricial changes either with or without a permanent perforation.

Mastoid swelling merely denotes a spread of infection to the superficial periosteum—a periosteitis—and may or may not arise according to the anatomical structure of the mastoid process. Other more reliable signs are otoscopic, and perhaps require more specialized training. Such evidences are to be found in a sagging of the posterior meatal wall and adjacent portions of the tympanic membrane. A profuse purulent discharge filling the meatus and rapidly re-appearing as fast as the external canal is cleansed is, however, almost invariably indicative of antral infection.

Pain and tenderness over the mastoid are valuable signs, but need not necessarily be present. Early mastoid pain and tenderness, which are frequently present at the outset of the otitic inflammation before middle-ear drainage is established, should not be confused with gross infection of the mastoid. Such early symptoms usually subside with free middle-ear drainage.

Temperature as a sign of mastoiditis is misleading. Indeed, quite commonly one finds gross infection in the antrum with perhaps exposures of the dura mater and lateral venous sinus, and yet with no pyrexia and little or no pain.

Drainage of the mastoid antrum

As soon as infection of the mastoid antrum is recognized as the cause of the persistent otorrhœa it should be immediately drained by the simple conservative (Schwartz) operation. It is an operation to those accustomed to aural surgery practically devoid of risks, and one so successful in securing perfect recovery with preservation of hearing as not to be neglected. An unrecognized antral infection may, it is true, gradually

subside, but with the risk of a permanent discharge, some degree of deafness and tinnitus, and all the risks contingent upon a chronic suppurative otitis media.

Space will not permit me to debate the controversial question as to whether mastoid drainage should be established early or late in the course of the infection. Surely there is only one time for drainage, namely, the correct time, which only experience can decide. To precipitate surgery in very virulent infections is wrought with great danger, and yet delay may be disastrous.

Malaria and Its Treatment

(From the *British Medical Journal*, 21st September, 1935, p. 552)

THE pressing need for an institute in Great Britain in which research on the chemistry of drugs for treating malaria and other diseases could be carried out was referred to at the meeting of the Chemistry Section of the British Association on Monday, 9th September. Colonel S. P. James, who opened the discussion, gave some interesting figures of the amount and cost of antimalarial drugs actually used, and of the morbidity of the disease. The Government had had to foot a bill of £350,000 for treatment and preventive measures in the Ceylon malaria outbreak, 14½ tons of quinine costing them £50,000 and £20,000 being paid for the German drug atehrin. Even the small island of Mauritius had spent the sum of 35,00,000 rupees since 1909 in fighting malaria, and Lagos had spent more. During the great war 70,000 British soldiers were ultimately put out of action in the Salonika campaign, while both the French and the Germans suffered equally badly. It was estimated that at the present time three and a half million persons die of malaria every year, most of the deaths occurring in parts of the British Empire. Though we disbursed nearly £500,000 on the purchase of quinine, yet our expenditure for research into the solution of the malaria problem amounted to barely a two-hundredth part of this sum. It was necessary to discover new drugs to supplement quinine treatment and to improve on it. The two important new antimalarial drugs—plasmoquine and atehrin—discovered by German chemists during the last eleven years were, added Colonel James, in some ways superior to quinine, but for benign tertiary malaria the latter was more effective. In spite of the humanitarian, economic, and imperial importance of antimalarial drugs there was, in this country, backwardness in research into their chemistry. In an account of investigations which had taken place under his direction, Professor R. Robinson stated that although twenty-four synthetic drugs had been discovered, none of them had the required effectiveness, and research had now reached a stage where further advance was impossible without adequate funds and more laboratories. Chemists needed a certain psychological stimulus, while chemical and biological co-operation could be made satisfactorily only when conducted under one roof; that was why a national institute for research in chemical therapy should now be founded. One contributor to the discussion was Professor Schulemann of Elberfeld, who attributed German successes in the production of plasmoquine and atehrin to the invention of new methods of testing the properties of synthetic substances by biologists. Plasmoquine was the thirty-fifth substance in a certain series, and since 1924 only one other effective substance had been found. The mode of operation of the two synthetic drugs was obscure, but some interesting facts were illustrated by experiments on mice. It was found that a joint application of the two drugs might produce abdominal pains, whereas if one were given immediately after the other there was no such effect. Mice could be killed if given the drugs on an empty stomach, but after a meal this did not occur. Yet if some of the gastric juice from these mice was injected into others which had had

nothing to eat they would die. This showed how drugs might be absorbed on the surface of food particles.

Therapy of Psoriasis

By THEODORE CORNBLEET

(From the *Journal of the American Medical Association*, Vol. CV, 13th July, 1935, p. 115)

THERE is no disorder more capricious in its responses to therapeutic measures than is psoriasis. Remedies that at one time are effective are valueless at another in the same person. The mildest agents may be helpful at first, and then the most powerful may not suffice to make an impression on the condition when it has reached an intractable state. There are no specifics and no known causes to attack. Out of the almost countless number of remedies proposed, only a few are worthy of mention as being relatively dependable.

One of the characteristics of psoriasis is the recurrence of the eruption at intervals. The periods of freedom may range from only a few weeks to many years. The aim of the treatment is then to clear up the eruption that is present. No promise for the future can be safely made. The treatment must be carried out in a thorough fashion until every trace of the lesions is removed. Any remaining lesions predispose to an early recurrence. As with many other dermatoses, the attack on psoriasis is by both general and local measures.

GENERAL MEASURES

The patient is given a thorough physical examination, and anything abnormal is corrected. The treatment for the skin condition itself proceeds as follows:

1. *Diet*.—A low protein diet has been advocated by many, who believe that it is helpful to reduce or entirely

Low fat diet

Forbidden:

All greasy soups.
All sausages and delicatessen, except frankfurters made of lean meat.
All fat meats, such as pork, mutton, fattened chicken, duck, goose, eel, herring, salmon, carp and other "rich" fish, roe and egg yolk.
All cheeses, except cottage (cream) cheese.
All fats (bacon, butter fat, palm, margarine, oil, cream, butter, whole milk, butter-milk and the like).
Meat may be roasted with some butter but the fat must be removed from the gravy by letting it get cold.
Cakes, cookies, whipped cream, butter cookies.

Allowed:

Lean soups (fat removed after letting it get cold); white of egg.
Lean beef (roast beef, boiled beef and so on).
Lean veal, lean venison (rabbit, deer and the like), lean ham.
Lean fowl (squab, chicken, partridge).
Lean fish (pike, cod, pickerel and others).
Sugar, malt, honey, raspberry juice and other fruit and berry juices.
All kinds of fruit and berries, raw or preserved.
Flour, rice, cream of wheat, potatoes, macaroni, noodles.
All kinds of vegetables, prepared without butter or fat.
Bread, white or rye bread, zwieback, toast, rolls.
Skim milk.

eliminate animal foods, including in this meat, eggs, poultry and fish, and in addition to forbid the use of peas and beans and fermented cheese. Recently a low fat diet has been advocated as more rational, because it is believed that in the psoriatic patient a disturbance of fat metabolism exists. Fat should be restricted to 20 gm. a day (10 gm. for children) including the fat used for cooking, and such diet must be continued for many months, as the effect does not appear for weeks or months and a relatively low fat diet must be continued indefinitely, as the psoriatic predisposition persists. The weight must be watched.

2. *Climate*.—Psoriasis is generally worse, or recurs only, during the winter season and usually improves with the appearance of warm weather. Many patients improve when they go to a warm, equable climate, and they may thus at times prevent the recurrences that they otherwise get with the advent of cold weather. Psoriasis does, however, occur in warm climates; but it is less prevalent in these. A resident in a warm climate

may derive benefit from a temporary change in residence even if it be to a colder one. A change in environment often is helpful even if only temporarily. A sea voyage or a trip to the seashore is said to be particularly helpful.

3. *Drugs*.—(a) Arsenic is, of all the internal remedies advocated, the most important. It sometimes will clear an eruption without the aid of local applications. It should never be used with an acute or progressive eruption. It should be used only when the eruption has become subacute or chronic or is stationary. As arsenic may lead to unfavorable changes when long continued, it should be used only at intervals. It is well to start with a small dose and to increase the dosage up to tolerance. When symptoms such as puffiness of the eyelids, edema of the ankles or gastro-intestinal disturbances are seen the dosage should be slightly reduced. There are some who believe it should be used only as a last resort, because it may lead to such untoward results as keratoses and epitheliomas, as well as to other damage. Solution of potassium arsenite (Fowler's solution) is the form of arsenical mostly used. Commencing with a dosage of three drops in water twice a day, this is increased by one drop each succeeding day until a maximum of from 10 to 15 drops is taken or until symptoms of intolerance appear. After a three months' use it is well to give the patient a rest from arsenic. It may be recommenced after a two to three months' interval. One should always write 'do not repeat' on the prescription, for many cases of chronic arsenic poisoning result from unsupervised continuance of the drug.

(b) Salicylate is held in high favour, particularly in early acute cases with considerable itching, in which arsenic is contra-indicated as it makes the itching worse. Sodium salicylate is generally used. It is prescribed in doses of 0.6 gm. with an equal amount of sodium bicarbonate to be taken freely diluted three times daily (prescription 1).

(c) Alkalis are used by many and are particularly favoured in gouty or rheumatic subjects. They may be combined with salicylate (prescription 1).

PRESCRIPTION 1.—Salicylate and Alkali

R	Sodium salicylate	10.00 gm.
	Sodium bicarbonate	10.00 gm.
	Cinnamon water	60.00 c.c.
	Syrup of cinnamon (N. F., VI) to make		120.00 c.c.

M. Label: Two teaspoonfuls in water three times daily after meals (in acute itching stage).

(d) Of other alternatives, antimony is sometimes of service in acute progressive cases. Other agents that have been recommended are colchicum, potassium iodide and mercurous iodide. Arsphenamine has been advocated by some but, except when there is a coexisting syphilis, it is questionable whether its use is justified. Thyroid and pituitary are said to be of value. As will be seen, there are many possible remedies but there is no reliable one.

4. *'Proteotherapy'*.—(a) Autohemotherapy: This method has gone through alternating periods of great favour and disfavour in psoriasis. Some feel that by itself it will clear many of the eruptions. There can be no question that at times it is of distinct benefit and that it often increases the effectiveness of other remedies. Twenty c.c. of whole blood is removed from the vein and injected intramuscularly, before clotting, generally into the gluteal region, every fifth day.

(b) Autoserotherapy: Blood, 50 c.c., may be removed, allowed to clot and centrifugated under sterile conditions. The serum is then injected intramuscularly or intravenously.

LOCAL THERAPY

General measures alone usually do not suffice to clear up an eruption. They require the aid of local applications.

1. *Removal of scales*.—The removal of scales that have accumulated on the lesions and offer an inert barrier to the effective action of the medicaments must

precede all local treatment. It may be accomplished by daily warm baths with liniment of soft soap ('tincture of green soap') and water. An alkaline bath, made by dissolving one or two teacupfuls of sodium bicarbonate in the bath, assists in the process. Following the bath the softened scales are brushed off with a Turkish towel. A stiff brush may be required to complete the removal of the scales. The skin may become dry as a result of this process and some bland grease or oil may be rubbed into the skin, which also helps to soften and remove the scales. Salicylic acid 5 to 10 per cent in petrolatum (prescription 2) applied to the lesions is particularly helpful toward removing obstinately adhering scales.

PRESCRIPTION 2.—Salicylic acid ointment

R	Salicylic acid	3.00 gm.
	Petrolatum	30.00 gm.

M. Label: Apply locally overnight (to aid in removal of scales).

2. *Soothing applications.*—Care must be used in the acute types or in the generalized forms not to use too stimulating an agent lest the skin be irritated and the eruption converted into an exfoliative dermatitis. In psoriasis, salves act better than lotions. In the acute forms a soothing ointment, such as ointment of rose water ('cold cream') or boric acid ointment, is likely to be found useful. As the eruption becomes less acute, more and more stimulating medicaments may be added; but the action of such applications should be closely watched and they should be promptly discontinued and bland ones substituted with the first signs of extension of the eruption or irritation of the surrounding skin.

3. *Irritative applications.*—These for the most part are reducing agents. The preferred ones are powerful.

(a) *Chrysarobin* is one of the most effective. Chrysarobin itself should not be used on the hands, face or scalp because it colours the normal skin deep brown and the hair yellow and it produces conjunctivitis. It may be used in ointments with petrolatum as the base in strengths of 1 to 10 per cent. After the application has been made to the lesions, it is sprinkled with talcum. After several days (from one to ten days, with an average of five days) the surrounding skin is seen to have become reddened. The chrysarobin ointment is then discontinued and a bland one used instead such as zinc ointment or boric acid ointment. As chrysarobin is irritating not only to the skin but also to the kidneys, patients having extensive application of this agent must be closely supervised. Discutient (scale removing) and irritative treatment may be combined as in a compound chrysarobin and salicylic acid ointment (Unna and Dreuw) useful for local scaly patches (prescription 3). From one to three days following the application of this ointment a brownish crust forms on the surrounding skin and the patches of psoriasis scale intensely. Bland ointment may then be used together with baths to remove the crusts and scales. After a few days the chrysarobin preparation may again be used, to be followed as before by simple oils or greases. Several such alternations are usually effective.

PRESCRIPTION 3.—Compound Chrysarobin and Salicylic Acid Ointment

R	Salicylic acid	10.00 gm.
	Chrysarobin	20.00 c.c.
	Oil of cade	25.00 gm.
	Soft Soap	30.00 gm.
	Petrolatum	100.00 gm.

M. Label: Apply to patches. (Useful on subacute, scaly lesions).

Less efficient than the ointments of chrysarobin are the chrysarobin varnishes. These have the advantage, however, that they may be better confined to the lesions themselves and help to spare the clothing, which otherwise is discoloured a mahogany brown stain that requires chlorinated lime or benzene for removal. A 7 per cent solution of chrysarobin in chloroform may be painted over the lesions. When the chloroform evaporates, a

fine powder remains, which is then covered over with flexible collodion. Simpler but less effective is a 7 per cent solution of chrysarobin in 'traumatizin', which is a 10 per cent solution of gutta percha in chloroform to which 2 per cent of salicylic acid may be added. When the films begin to peel, they are removed and replaced with a new application.

(b) *Tars* of various types, such as wood tar, oil of cade or coal tar, are preferred by some physicians, who no longer use chrysarobin because of its obvious disadvantages and because it may vary in its effectiveness from sample to sample. The tars may be used in 5 to 10 per cent strengths in zinc ointment or paste of zinc oxide (Lassar's Paste). They may be put in flexible collodion in somewhat greater strengths, from 10 to 20 per cent. Tar may be used with other agents such as sulphur or soft soap, as in the long used compound sulphur ointment (Wilkinson's ointment).

They may be used in liquid form and undiluted but are usually best dissolved in alcohol in 10 to 25 per cent strengths and salicylic acid 5 to 10 per cent, and soft soap 25 to 50 per cent may be added (prescription 4). The liquid form may be painted over the patch after removal of the scales following a bath. When the liquid tar preparation has dried for a while,

PRESCRIPTION 4.—Salicylated Oil of Cade Pigment

R	Salicylic acid	10.00 gm.
	Oil of cade	25.00 c.c.
	Soft Soap	25.00 gm.
	Alcohol	100.00 c.c.

M. Label: Paint over patches, permit to dry, and wash off excess in bath.

the patient may be returned to the bath and the excess of tar finally washed off. It is always well to begin the use of tar preparations with the weaker concentrations and build up to the stronger, because they may at times surprise one with an unexpected reaction; for the tars may produce toxic symptoms, such as vomiting and diarrhoea, and kidney irritation. These promptly disappear when the application is removed. Betanaphthol and resorcinol may be looked on as colourless tar succedanea, to be employed in 5 or 10 per cent solutions or ointment when the coloured tar preparations are objectionable.

(c) *Ammoniated mercury* is mostly used for the scalp. The strength is 10 per cent, and a base is used that will wash out of the scalp readily, such as rose water ointment. Salicylic acid may be incorporated to advantage in proportions of 3 to 5 per cent. Such an ointment (prescription 5) may also be used on the glabrous skin. The urine should be watched for signs of kidney irritation.

PRESCRIPTION 5.—Ammoniated Mercury and Salicylic Acid Ointment

R	Ammoniated mercury	3.00 gm.
	Salicylic acid	5.00 gm.
	Rose water ointment	30.00 gm.

M. Label: Apply to scalp.

4. *Irradiation.*—(a) Ultra-violet rays are most useful in the acute types of psoriasis as well as in the superficial types in folds. Some believe that their use at intervals, after involution of an eruption by other measures such as x-rays, may materially prevent recurrences. The exposures should be given twice weekly and to the point of obtaining definite reactions with pigmentations. This method is not quite so effective as that with the x-rays but is free from possibility of dangerous sequelae. A method that has been particularly effective is the combined use of 1 to 5 per cent coal tar ointment with ultra-violet rays. The ointment is spread on the skin about one-eighth inch thick. At daily intervals the excess ointment is wiped off with olive oil, a thin film of the crude coal tar being left. Irradiation with a mercury quartz lamp is then carried out. This is said to be particularly effective in the exfoliative dermatitis following psoriasis. This form of treatment should be carried out only in a hospital or where the patient can be closely supervised; but in modified form it can be used for ambulatory patients.

(b) When judiciously used, roentgen therapy is effective, painless and clean and requires no care on the part of the patient. Once he learns of it, he is apt to want it in preference to all other remedies. Its excessive use, however, is dangerous. Psoriasis is usually a recurrent disease and the repeated use of x-rays over an area is liable to lead to serious sequelae such as telangiectasis, keratosis and epitheliomatous degeneration. If from four to six weekly doses of a quarter unit (75 roentgens) are ineffective, it is wisest to discontinue the x-rays, as the eruption is apt to be resistant to further exposures. On the scalp it is perhaps best to employ weaker doses of about one-eighth unit (38 roentgens) once weekly. For the nails a quarter unit of filtered rays to the tip of the finger as far proximally as a half inch from the cuticle is most effective. Strong local remedies should not be used in conjunction with the x-rays. A 5 per cent ammoniated mercury ointment may generally be used with safety. Some believe that the psoriatic skin is more sensitive to x-rays than the normal. As with other dermatoses, dosage should be reduced for patches occupying the more tender skin in the folds, such as submammary and axillary. Psoriasis of the auditory canals may be treated with 0.5 unit filtered rays at intervals of two to three weeks. The surrounding skin should be carefully shielded. At times, lesions of psoriasis may involute promptly and recurrences be resistant, while x-rays are ineffective in some from the start. If roentgen treatment is persisted in without effect, the lesions are apt to become resistant to other measures as well, and increasing the dosage to obtain results leads to dangerous sequelae. X-rays should not be employed in eruptions that recur quickly or that are acute and spreading.

(c) Radium is of limited use in psoriasis. It is valuable in tube form in such places as the auditory canal. A silver tube screened with rubber and placed within the canal to give from 40 to 50 millicurie hours generally produces excellent results.

(d) W-rays or Grenz rays may be useful for hairy parts or where the underlying tissues may be injured by x-rays, such as the testes. The dosage should be such as not to provoke sharp reactions.

Surgical Shock

(From the *British Medical Journal*, 6th April, 1935, p. 706)

THE outstanding feature of primary shock is a fall in arterial pressure, but if the fall is such that the blood pressure remains at or above 80 mm. Hg. the oxygen requirements of the tissues may still be satisfactorily met. If, however, the blood pressure falls to about 70 mm. Hg., and is maintained at this level for some time, secondary shock supervenes, and the consequences are extremely serious. It is clear that there will be a diminution in oxygen supply to the tissues, with consequent fall in metabolic rate; the skin is cold and clammy, the pulse is thready, and the heart beats rapidly; respiration is shallow and poor; the patient is weak and toneless; thirst is experienced, but the patient may be unable to retain fluid in the stomach; finally, unless adequate measures are taken, the outcome is fatal. From the point of view of aetiology one need only consider primary shock, since the phenomena of secondary shock call for no special explanation, as they are the normal and anticipated consequences of a maintained extreme hypotension.

In a recent series of papers a valuable account has been given by a number of observers of modern views on primary shock. Professor W. B. Cannon presents a valuable review of the evidence for various theories. He rightly points out that a weakened heart is not a serious aetiological factor. The heart, even in such an emergency, is well able to make the additional effort required of it. Discussing the commonly enunciated view that shock is due to loss of vasomotor tone

(with consequent stagnation of large volumes of blood in the splanchnic region) Cannon draws attention to the fact that the fall in arterial blood pressure is responded to by a vaso-constriction through the carotid sinns. It is, of course, conceivable that a long-continued tissue anoxemia may lead to such malnutrition of nerve cells that a loss of vasomotor tone may occur, but it seems probable that by that time the situation is one of deep secondary shock. One of the main causes of shock seems to be in the reduction of blood volume, on which all observers are agreed. In some at present rather obscure way the blood volume is reduced below the minimum capacity of the vascular system, so that the vessel walls cannot contract down on the blood. The modes of production of this remarkable loss of blood fluids are the bases of several theories of causation. The theory that this is brought about by a toxic, histamine-like substance liberated from injured tissues is an old one, and dates from war-time observations. While there is still a considerable school of support for this view, the newer observations of several American workers have shown that the hypothetical toxic factor is not detectable (indeed, muscle tissue is remarkably poor in histamine) and that the blood lost from the circulation is really present in the injured tissue itself. The toxic theory cannot be dismissed merely on the grounds that muscle is poor in histamine, for there are certainly other powerful vaso-dilators in the muscles, and these might conceivably be concerned with the early stages of shock.

The probable involvement of the autonomic nervous system as an aetiological factor is suggested by a large number of facts—for example, pain and fear may bring on symptoms like mild shock; abdominal operations with manipulation of the viscera (hence stimulation of sympathetic afferents) may cause a fall of blood pressure to shock levels. Experiments by Freeman have demonstrated that stimulation of the sympatho-adrenal system may produce the shock syndrome, with fall in blood pressure and loss of consciousness. . . . must be remembered that . . . while causing splanchnic and cutaneous vaso-constriction, produces dilatation of the vessels of the muscles—a state of affairs that might readily allow of the passage of fluids into the muscles. Nevertheless, it is difficult to see how so complex a matter as filtration of blood plasma into muscles could explain the collapse which every medical man has seen in some cases on merely showing the patient a syringe with which blood is to be drawn. Psychogenic shock of this type seems surely to be related to some immediate and considerable diminution of the cerebral circulation; the consequent temporary collapse by serving to remove the psychological stimulus allows of correspondingly rapid recovery. How this type of shock is produced is unknown. Some experiments by Heuer and Andrus are of interest. These workers observed that aqueous extracts of fatally strangulated intestinal loops could, on intravenous injection into dogs, give rise to symptoms of shock, vaso-dilatation and loss of plasma from the blood. This effect would be antagonized by extracts of adrenal cortex, which is of great interest in view of the importance of the adrenal cortex in regulating the exchange of fluid between blood and tissues.

The special problem of traumatic shock following violent blows to a limb has recently been very carefully studied by O'Shaughnessy and Slome in the anesthetized cat. Using many modern methods of physiological research it was possible to demonstrate conclusively that 'a toxæmia due to the elaboration of histamine, or any other depressor substance in the traumatized area, plays no part in the syndrome of traumatic shock'. These authors make a strong case for local fluid loss and nervous stimuli in the aetiology of shock. Spinal anaesthesia before the injury delayed the onset of shock in spite of great fluid loss; also, spinal anaesthesia induced during the period of extreme circulatory failure led to marked recovery of blood pressure. This noteworthy paper, in conjunction with the findings of several American workers, accentuates

the immense importance of the elimination of nociceptive nervous stimuli in the prevention and treatment of traumatic shock.

The Indications and Results of Phrenic Nerve Operations

By H. M. DAVIES, M.D., M.Chir. (Camb.)
F.R.C.S. (Eng.)

(From the *Lancet*, 24th August, 1935, p. 418)

THERE are three operations for paralysing the dome of the diaphragm. There is *phrenic evulsion*. It is generally estimated that at least 10 cm. of the nerve must be torn out in order to be sure that the continuity of all accessory nerve bundles with the distal end of the phrenic nerve have been interrupted. Then there is *phrenicectomy*. This operation demands the section of a length of the main phrenic nerve and of all accessory nerves including the filaments to the sub-clavius muscle. The third operation is the *phrenic crush*. In this operation the main phrenic nerve is crushed and all accessory nerves are divided. The effect of the crush lasts from two to six months or even longer; regeneration may even fail to take place.

The immediate effect of these operations is paralysis of the hemidiaphragm; the muscle-fibres degenerate, and the dome becomes a sheet of fibrous tissue. It takes about four months for this process to become complete.

As a result of the paralysis there are three changes of the dome—namely, a rise into the thorax, a loss of tone, and a cessation of the normal respiratory movements. The dome either becomes immobile or shows paradoxical movements, sometimes with normal respiration but more often only with forceful efforts such as sniffing. Each of these changes has a separate or combined action on the thorax, the lung, and the disease.

Under normal conditions the rise of the diaphragm into the thorax during expiration is due to three factors: the relaxation of the muscle-fibres, the negative pressure in the pleural cavity, and the positive pressure in the abdomen. The descent during inspiration is, of course, due to contraction of the muscle-fibres. With the dome paralysed, it ascends into the thorax as a result of the difference between the negative intrapleural and the positive intra-abdominal pressures. When the lung is affected by chronic tuberculosis, although there is loss of elasticity of the lung, there are fibrous tissue changes which may more than counteract the loss of elasticity and, other things being equal, will increase the intrapleural negative pressure, and so exert an abnormal upward drag on the dome. *Per contra*, in a chronic invalid there may be loss of tone of the abdominal muscles and possibly visceroptosis, and the upward thrust on the under surface of the dome will be lessened.

There are other pathological states, however, which may interfere with the post-paralytic rise of the dome. Thickening of the pleural membranes, particularly of the diaphragmatic pleura, superimposes on the dome a tough layer of tissue which yields but grudgingly to the forces above and below; whilst obliteration of the costophrenic sulcus ties down the margin of the diaphragm. When, further, the pleural thickening is generalized and the interlobar septa are also involved, the chest wall itself tends to become contracted, fixed, and immobile, and so scarcely alters the intrapleural pressure during inspiration.

The extent of the rise of the dome varies greatly after phrenicectomy. It may be barely 1 cm. or as much as 10 or 11 cm.; very rarely has it reached a height of 14 cm.

EFFECTS ON THE LUNG

Before we can appreciate the rationale of the indications and the results, it is essential to understand not only the changes in the diaphragm but also the

effect of these on the lung and the thorax in general. There is the influence on the lung of the paralysis of the hemidiaphragm, and of the loss of tone. There is also the influence of the rise into the thorax.

The diaphragm, by its descent, is responsible for the expansion of the lower and posterior parts of the lung; with one half paralysed there is the loss of this expansion force. The consequent deficiency of air entry into these areas of the lung can be observed clinically. To the loss of tone must probably be attributed the benefit of the diminution or disappearance of certain symptoms such as the diaphragmatic cough.

The effect of the rise of the dome on the lung is one which has given cause for much conjecture and argument. In the normal lung there is little doubt but that the greater part of the reduction in the hemithorax is absorbed by a collapse of the base of the lung due to relaxation of the elastic tissue; the higher the rise, the greater is the extent of the lung affected, but it is very unlikely to include the apex. If, however, there are consolidation changes at, say, the base of the lung that part is uninvolved, but the nearest areas of healthy lung tissue will contract.

When there is chronic fibrosis in the apex or upper lobe as a result of tuberculosis, a different mechanism comes into play. This mechanism is identical in principle with that found in the production of a selective collapse by artificial pneumothorax. The elasticity of the healthy parts of the lung will cause the partial collapse of the lung, if for any reason the negative pressure is reduced, but the elastic tissue being perfect it will at once yield again to the expanding force of an increased negative pressure. Pathological fibrous tissue is also ready to contract, given the opportunity, and so powerful is its contracting force that it can drag the chest wall and mediastinum towards each other, exerting a force of which the elastic tissue is quite incapable. When a rise of the dome occurs and the hemithorax becomes reduced in size, the elasticity in the adjacent lung fields causes a reduction of these areas; but the fibrous tissue in the upper lung field is even more responsive to the reduction in the hemithorax; it therefore contracts. During inspiration the increase in size of the chest and the increase in the intrapleural negative pressure calls for a re-expansion of the lung. The elastic tissue responds to this, but the fibrous tissue does not. The result is a gradually progressive selective collapse of that part of the lung which is fibrosed.

There are other factors, however, which have to be taken into consideration. Reference has already been made to the possible impeding influence of changes in the diaphragmatic pleura. Thickening of this membrane must interfere with the rise of the dome, and yet at times it is surprising to what extent the dome may rise after phrenicectomy despite a known thickening of the membrane. The filling-up and obliteration of the costophrenic angle does inevitably tie down the dome.

Further the presence of dense interlobar adhesions, the outer edge of which are fixed to the chest wall and with the radiogram showing a curved outline convex upwards, is almost certain to act as a barrier guarding the upper lobe from influences below it.

INDICATIONS FOR PARALYSING THE DIAPHRAGM

It is essential, when considering the indications for paralysing the phrenic nerve, to appreciate the object of the operation. There seems to be a prevalent view that it is done for the cure of pulmonary tuberculosis. Profound disappointment must be the fate of those who operate under this misapprehension. Phrenic paralysis often relieves symptoms, especially when it has been correctly advised to this end rather than to the treatment of the disease, but it is not a radical operation for 'cure'. It is but an asset in the treatment of the disease. Used properly, it is an immensely valuable one, helping to overcome or to diminish mechanical changes which are interfering more or less seriously with the progress of recovery. Like other

measures, it is an accessory to sanatorium treatment in the endeavour to increase the resistance of the body to the disease, the effective fibrosing of active tuberculous foci and the obliteration of cavities.

It is often stated that one of the indications for phrenicectomy is failure of artificial pneumothorax; in other words that a phrenicectomy should be done on every case on which an artificial pneumothorax has been tried and failed. It is possible that I have said this myself in the past, but I now assert emphatically that every case suitable for artificial pneumothorax is not necessarily suitable for phrenicectomy.

Artificial pneumothorax is attempted in cases of pneumonic tuberculosis and also in cases of the cascating, exudative form of disease. Possibly the immobilization of the dome which has been paralysed may be advantageous in a purely basal case; but, if the base is not involved and is the comparatively healthy part of the organ, phrenicectomy is definitely contra-indicated, since it will bring about collapse of the healthy part of the lung and leave the diseased pneumonic area unaffected.

Then again, artificial pneumothorax is frequently done in the hope of collapsing cavities, usually in the upper lobe or apex. When these cavities are large or are surrounded by dense fibrous tissue, it is expecting almost the impossible to try to obliterate them by a phrenicectomy. The operation is useful for some cavities, but not for this type. Nor is a lung with old-standing fibrosis and one or more cavities likely to benefit by phrenicectomy. If the condition is unilateral, the indication is a thoracoplasty, in some cases without even the preliminary trial of an artificial pneumothorax. A phrenicectomy would be valueless and might even be detrimental.

The indications for phrenicectomy in the treatment of pulmonary tuberculosis are divisible into four groups:—

- (1) For the treatment of pulmonary disease. In these cases the extent of the rise is the important factor.
- (2) For the treatment of past or present pleural involvement. In this group both the rise and the immobilization play an important part.
- (3) For the treatment of symptoms. In these cases it is not so much the rise of the muscle as the loss of tone and the immobility that is necessary.
- (4) In conjunction with other surgical measures.

THE PULMONARY LESION

The chronic fibrotic lesion is one of the types most responsive to phrenicectomy, but it is not all fibrotic lesions of the upper lobe which will respond to phrenicectomy. If the fibrosis is very dense and there are cavities, it will need a very exceptional rise of the dome to influence this, and even with such a rise, failure of an efficient collapse is more than probable. In such cases the cap of the lung is almost always firmly adherent and allows of no shifting of the lung surface; the whole of the collapse requisite to relax the fibrous tissue and to obliterate cavities would therefore have to be obtained by the upward displacement of the central part of the lung as a dome into the apex—an obvious impossibility. The probability therefore of a dense apical cap of adhesions and equally of dense interlobar thickening which acts as a barrier between the upper and lower segments of the hemithorax must be considered contra-indications. These cases, moreover, are eminently suitable for the major operations which will produce a permanent healing impossible by lesser measures.

A moderate degree of generalized fibrosis is, on the other hand, an indication for phrenicectomy. This type of case, even if the condition has been sufficient to produce some flattening of the chest wall and displacement of the mediastinum, may respond most favourably. It is in this group that is found pre-eminently the case which, having made considerable progress with rest in bed, reaches a stage with persistence of cough, sputum, and mild pyrexia beyond which

it seems incapable of responding, but after a phrenicectomy improves again progressively and may become symptomless.

Cavities surrounded by dense fibrosis or with thick walls cannot be expected to be favourably influenced by phrenicectomy. Small cavities, on the other hand, without well-defined walls, whether in the base, apex, or region of the hilum, and which have resisted rest in bed, may become obliterated following on a fairly high rise of the dome. The possibility of success is certainly sufficient to justify the operation.

It must be admitted, however, that there are very divergent views on the value of phrenicectomy in the treatment of cavities. Patronikola, for instance, says that out of 100 cases, 4 only were benefited. Russell reports control in 9 out of 21 cases at the Cheshire Joint Sanatorium in which artificial pneumothorax had failed or been ineffective. The results of Nehil and Alexander are very interesting: of 53 cases with a cavity of 2 cm. or less, closure occurred in 65 per cent; of 63 cases with a cavity of 2 to 4 cm., closure followed in 36 per cent; and in 32 cases with a cavity of 4 to 6 cm., closure occurred in 22 per cent. When the location of the cavity was in the upper third of the lung, closure was recorded in 40 per cent; of those located in the middle third, 31 per cent closed, and of those in the lower third, 29 per cent closed.

Phrenicectomy has many advantages over artificial pneumothorax. It is a single operation and the risks of complications are infinitely fewer; if successful, it does not interfere with future work as may be the case with an artificial pneumothorax. It is pre-eminently the moderately localized proliferative lesion, whether of the upper or lower lobe, which has responded up to a certain stage, yet incompletely, to rest in bed, for which phrenicectomy is indicated as the first line of attack in preference to artificial pneumothorax. The operation should take precedence also in some cases of isolated thin-walled cavities, particularly when a cavity develops in the contralateral lung in a case under treatment by artificial pneumothorax. The combination of phrenicectomy on the one side and of artificial pneumothorax on the other may prove very valuable in the treatment of bilateral disease.

PLEURAL INVOLVEMENT

The second group of cases for which phrenicectomy is indicated is that in which an old or recent pleurisy has been responsible for thickening of the basal costal and diaphragmatic pleural membranes with obliteration of the costophrenic sulcus, and fixation and possibly distortion of the diaphragm. In these cases comparatively little immediate rise can be expected; nor is that the object of the operation so much as the paralysis and loss of tone.

The third group of indications is for the treatment of symptoms, a group far too often neglected. The first and most important, though not the commonest symptom which may call for an emergency phrenicectomy is hæmoptysis. Several cases have been recorded of intractable bleeding for which artificial pneumothorax had proved impossible but which have stopped abruptly after phrenicectomy; in some the bleeding came from the upper and in others from the lower lobe. Alexander gives preference to phrenicectomy over pneumothorax for the arrest of bleeding.

RELIEF OF SYMPTOMS

So far I have discussed the treatment of the disease. With healing there must naturally be improvement of symptoms, lessening of cough and sputum, pyrexia, disappearance of tubercle bacilli, and so on. The improvement in the cough and sputum may occur long before there is time for healing processes to take place. A working diaphragm is not necessary for bringing up and expelling sputum. Often as a result of the disease spasm, and this actually hampers expectoration. With paralysis of the dome, the full force of the contraction

of the abdominal muscles is transmitted directly to the thorax, and facilitates expectoration.

Adhesions between the lung and diaphragm may cause a diaphragmatic cough—a spasmodic cough which is started by movement, laughing, even talking. This can be abolished by paralyzing the dome, to the intense relief of the patient and with considerable benefit to the lung. The morning vomiting brought on by the pumping of the dome on the stomach with the initial emptying of the bronchial tubes of accumulated sputum after sleeping can also be stopped by a phrenicectomy.

Patients who have had pleurisy, whether the associated disease is still active or quiescent or healed, may experience dragging aches, pains, or discomfort round the base of the chest. The relief that can be given by paralyzing the dome justifies the operation for this alone. Such pleurisies not infrequently implicate the pericardium, when the drug is liable to produce tachycardia on comparatively slight exertion. This too will be relieved by the relaxation of the dome.

AN ADJUVANT TO OTHER OPERATIONS

The final group concerns the indications for phrenicectomy in conjunction with other operative measures. The first to be considered is the combination with artificial pneumothorax. Reactions and effusions during the maintenance of artificial pneumothorax are more likely to occur and recur when there are adhesions which are stretched by each refill. Paralysis and rise of the dome may relax these bands and thus for the time being remove the irritation and lessen the tendency to reaction and effusion. If the adhesion is so placed that the tension is not relieved, no benefit will have been gained as regards these manifestations. Apart from this, phrenicectomy has no benign influence on effusions. It does, however, in certain cases undoubtedly enable the interval between refills to be lengthened.

The rise of the paralysed dome may aid somewhat in cases where the base of the lung is adherent or there is a progressive obliterative pleurisy. A high rise of the dome may be invaluable in certain cases of suspended cavity, converting occasionally an artificial pneumothorax which is a failure into a success.

When a lung, involved by a disease which produces fibrous tissue changes, has been long collapsed and is then allowed to re-expand, a considerable strain must be imposed on the originally diseased fibrotic area and on the walls of old cavities, when that lung re-expands. The hemithorax is admittedly smaller than at the onset, because the chest wall has shrunk and the mediastinum has come across, whilst the healthy alveoli have become emphysematous; yet it seems most advisable further to relieve the strain by raising the height of the dome by paralyzing it.

Finally, there is the much debated question of phrenicectomy in conjunction with major operations. There are certain cases in which it is advisable to have the dome paralyzed some time before the operation so as to help the cough and expectoration, reduce the pyrexia, and improve the general health of the patient. For these, a preliminary phrenic crush only should be done so that recovery of the function of the dome is returning approximately coincident with convalescence from the major operation. If a total thoracoplasty is indicated the motionless dome will, in my opinion, have a detrimental, rather than a beneficial, effect on the collapsed lung. When the operation is one localized to the apex or upper lobe, the raised dome is more likely to put healthy basal lung tissue out of action than to produce any appreciable collapse of the apex.

It is extremely doubtful if a paralysed dome has any influence in preventing an aspiration pneumonia during the operation. Its other supposed value as a test for the contralateral lung seems to me to be worthless.

The statement has just been made that a phrenic nerve crush should be done in preference to a phrenicectomy whenever the diaphragmatic paralysis is a prelude to a total or localized thoracoplasty or to an apicolysis. The phrenic crush is also the preferable

operation in every case where the base of the lung is not affected and the influence on the lesion is of considerable doubt. It is also preferable in cases with bilateral disease when the operation is an emergency one to check bleeding. Matson says that 'a return of diaphragmatic function can be expected in 25 to 30 per cent of all cases, unless all communicating or accessory fibres have been resected'. Bonniot and Foix noted a return of function in 8 per cent when the evulsed nerve was over 10 cm. in length, and in 29 per cent when the length was under 10 cm. Lindberg found that no improvement resulted when the total elevation of the paralysed dome was less than 3.9 cm. In 80 per cent of his cases there was a secondary rise averaging 2 cm.; the maximum rise was usually not reached under three months. Matson records a case with an initial rise of 3 cm., a further rise of 6.5 cm. in the ensuing year, and a total rise of 13 cm. by the end of the second year.

RESULTS

Many papers have been written and figures given showing the late results of phrenicectomy with the percentage 'cured', improved, and so on. The general opinion is that considerable benefit can be obtained in suitable cases. Yet there are a few like Gravesen who consider 'that the actual efficacy of the operation has been greatly exaggerated by many', and that the indications are very limited. He finds that there were 'only 27 cases (out of 153 available for "true statistical analysis") where we have any right to say the patients were healed as the result of the phrenic operation'. Those figures are, in my opinion (though not in Gravesen's), most encouraging, because I would again emphasize the fact that phrenicectomy must not be looked upon as a 'curative' measure, but as an auxiliary and ancillary measure to other forms of treatment.

For this reason I make no attempt to give figures as to results. It is not possible to produce anything like an accurate statement. In some cases the operation is done with a certainty of benefit to be gained either as regards the disease or the relief of symptoms; in others there is a reasonable possibility of benefit. In yet others a crush is indicated as, while the result is doubtful, there is a possible hope of success. In a disease like tuberculosis, with its disappointments and surprises, this success must be sought for, at times even at long odds.

Berry collected in 1930 the records of 4,697 cases of phrenic nerve paralysis with a mortality of 26 cases. Of the deaths 6 were due to bleeding from extraction of the nerve and 2 to a traumatic emphysema and empyema associated with a traumatic pneumothorax. These 8 cases were unquestionably accidents associated with evulsion of the nerve. Lung embolus and oedema accounted for 3 deaths, and dyspnoea and heart failure for another 3. There were 12 deaths from pneumonia and tuberculous dissemination. Of these 12, 5 were reported by Loewenthal who regarded the condition as an 'unspecific pneumonia' due to injury to the pleura while evulsing the nerve. Another possible explanation is that during evulsion the dome gets drawn up into the thorax. At the moment that the nerve filaments give way the diaphragm returns with a sudden, violent descent which may easily cause the aspiration into the lower lobe of secretion squeezed out into the bronchi during the period of elevation. Death from syncope has also been recorded at the moment of evulsion. It is phrenic evulsion not phrenicectomy which is the operation which carries the immediate grave risks. I have seen 3 cases of spontaneous, symptomless, partial pneumothorax occur within a week of evulsion.

The most important of the later complications are those due to the displacement of the stomach and duodenum and the dislocation of the oesophageal opening. Vomiting occurs very occasionally immediately after paralysis of the left dome, but usually subsides in a day or two. Digestive disturbances, flatulence, and hiccorygmi may last somewhat longer.

It is rare for these even to be serious in character or of lasting duration. The most troublesome complication in my series—and I am well on in my second thousand—has been the persistence of horchorygmi for eight months, when it rapidly disappeared. Digestive discomfort has been recorded after paralysis of the right dome due to traction on the first part of the duodenum.

Radiological examinations show, according to Longuet and Lamay, that with a high rise of the left dome the stomach is elongated and shows a large air space. Of more serious consequence is, however, the condition similar to that found with eventration of the diaphragm, a rotation, producing a partial volvulus of the stomach, causing a constriction across the length of the organ.

Symptoms may therefore be produced by constriction of the œsophagus, of the stomach, or of the duodenum. In the majority of the cases the symptoms are slight and transitory. Very rarely only are they of serious import, and they may then be associated with cardiac or pulmonary manifestations, such as tachycardia or dyspnoea. Dyspnoea of a mild grade may also be observed independently of the above complications. It may persist for two or three weeks and then subside as compensation and adjustment take place.

Favourite Prescriptions

By J. E. M. WIGLEY, M.B., M.R.C.P.

(From the *Practitioner*, Vol. CXXXV, September 1935, p. 352)

THE earliest Pharmacopœia of St. John's Hospital which I have been able to obtain was published in 1898, and is a more bulky book than either of its successors of 1912 or of 1926. Another revision, which does not differ appreciably in size from the one published in 1926, is in the press. One of the most notable differences is in the number of mixtures; in 1898 there were 37 mixtures, in 1912 the number was reduced to 31, in 1926 to 21, and in the forthcoming revision the number rises to 27, but this increase is largely due to an increase in the number of the honorary staff of the hospital, each member naturally ordering his own particular prescriptions. It cannot be taken to indicate any retrograde step towards a belief in the 'humoral' cause of skin diseases.

Another noticeable change is in the number of *balnea* or *medicated baths*; in 1898 these were 8, but by 1912 they were reduced to 4, at which number they have remained. Of these two only, the *balneum alkalinum* and the *balneum furfuris*, are used at all frequently. Quite rightly the sulphur bath has disappeared as it was always far more effective in causing sulphur dermatitis than in curing scabies. Strange to say, it is still used by certain public authorities. The medicated vapour baths of 1898 have completely disappeared, chiefly because they were found to be both an unreliable and an irritating method of using the particular drug. It is so much more satisfactory to inject a measured amount of mercury into the gluteal muscle than to irritate the whole skin, and still have a very remote idea of how much mercury has been absorbed.

Cautics, as such, too, have disappeared, though *Liquor hydrargyri acidi nitratis* is still the most popular in the treatment of lupus vulgaris. The solid stick of silver nitrate, 'lunar caustic', still has many valuable uses, but the modern treatment of neoplasms with radium and x-rays, of lupus with ultra-violet light from various sources, and of warts and similar tumours by various electrical methods, has done away with the necessity for many of the drastic, it might almost be said barbarous, methods of our ancestors.

One very useful addition, made in 1926 and retained, is the *Cataplasma amyli* for the making of which Sir Norman Walker gives such clear directions. It is a remedy which is far too little used, probably as it is too little known. It is certainly one of the very safest

remedies to apply to an inflamed, weeping or crusted surface and many cases of infantile eczema can be completely healed by its continued use alone.

The *creams* appear under that name in 1926, though the calamine cream has reverted to its original name of *Linimentum calaminæ*. It appears in the National Formulary as the *Lotio calaminæ oleosa*, though the consistency of it is really that of a cream. Cream applications are far less frequently used in general practice than their special virtues call for. They make a very excellent half-way house between a lotion, which so often proves drying as used by a patient who can only change his dressing morning and evening, and an ointment, which proves irritating to an inflamed, weeping or crusted surface. The ointment acts as a more or less waterproof covering, prevents evaporation and dams back the exuding serum, and many acute eruptions would be checked in their earlier stages by the use of a simple cream. The *Cremor zinci* is an excellent formula, as follows:—

R. Zincii oxidi	180 grains
Lanolini	240 grains
Liquoris calcis	}	..	of each 1 ounce
Olei olive		..	

Using this as a base 10 minims of ichthammol, or *Liquor picis carbonis* may be added so as to exert a more anti-pruritic effect.

Plasters number eight as compared with ten in 1898 but by far the most commonly used are varying strengths of salicylic acid for macerating horny excrescences, such as warts and corns, and salicylic acid combined with creasote which is chiefly used in the treatment of warty tuberculosis (*verruca necrogenica*).

The *gargles* have been reduced from four to two, chiefly because practitioners, and sometimes patients, are more discriminating in their choice of hospitals, and diseases of other systems of the body are seldom seen at a hospital primarily intended for diseases of the skin.

Unna's zinc gelatin is still retained (combined with ichthyol) as, in spite of the great influx of ready-made bandages, it still remains the best supporting application for many cases of varicose eczema and its frequently associated ulceration. As a protective or 'occlusive' application in many chronic itchy and 'lichenified' patches and even in self-produced or artefact eruptions, Unna's dressing is invaluable. In the National Formulary it is called *gelatinum zinci* (Unna's paste).

The sclerosing treatment of varicose veins, which really owes its great modern impetus to the shortage of men in the French army about 1915, is responsible for the appearance of the *injection quinine et urethane*. Opinions still vary greatly as to the efficacy of the various sclerosing fluids which can be used for the injection of varicose veins, but the majority of the staff at St. John's Hospital were of the opinion that quinine-urethane had more advantages than disadvantages, and so it was the one selected for inclusion in our Pharmacopœia.

Only two *liniments* appear in the latest Pharmacopœia, of which *Linimentum calaminæ* (which is the *Lotio calaminæ oleosa* of the National Formulary and of many other hospital pharmacopœias) is the chief. So many commercial firms put up an excellent preparation of this that it is seldom necessary to write the prescription for it, but the one given here makes up very well. It is:—

R. Calaminæ	40 grains
Zincii oxidi	20 grains
Liquoris calc.	}	..	of each ½ ounce
Olei sesami		..	

It may be used as a base for many other medicaments, and is undoubtedly the chief, if not the only, constituent of most of the 'beauty parlour' preparations sold under the enticing names of 'foundation lotion' and other similar titles. The *Linimentum acid salicylic* compound is a most useful application for

mild cases of dandruff or pityriasis sicca and is also mildly stimulating for seborrhœic types of alopecia:—

R Acidi salicylici ..	25 grains
Aleohol (60 per cent) ..	60 minims
Oleum ricini ..	to 1 ounce

For use in private practice the not very pleasant odour of the castor oil may be masked by a few drops of oil of lavender or rosemary.

Lotions

The lotions show a rather striking increase in number, as in 1898 there were 18 and now there are 28. This increase is partly due to listing small variations as different lotions, as, for example, *Lotio calaminæ cum pice*, which is calamine lotion with the addition of liquor picis carbonis, 8 minims to 1 ounce. The world-famous calamine lotion, like the liniment, is now put up so well by so many firms that writing of the detailed prescription is seldom called for. The formula favoured at St. John's Hospital is:—

R Calaminæ prep.	} of each 20 grains
Zinci oxidi	
Glycerini	30 minims
Liquoris calcis	300 minims
Aquam destillatam	to 1 ounce

It also masquerades under various attractive names of which 'sunburn lotion' is one of the most popular. A very effective though apparently not widely known value of calamine lotion is its mildly antiseptic and drying effect on the lesion of impetigo contagiosa.

Here it may be noted is the excellent *Lotio d'Alibour* or *Lotio cupri et zinci sulphatis* which is also in the National Formulary, and is very effective in the treatment of impetigo. The formula is:—

R Cupri sulphatis	4 grains
Zinci sulphatis	6 grains
Aquam camphoræ	to 1 ounce

A very useful lotion for the treatment of acne vulgaris is the *Lotio calaminæ cum sulphure*, which contains 10 grains of sulphur to the ounce of calamine lotion and is usually quite as efficacious as the *Lotio sulphuris et zinci*, the formula for which is:—

R Sulphuris præcipitata	} of each 15 grains
Zinci sulphatis	
Potassi sulphidi	
Aquam destillatam	to 1 ounce

Soothing and cooling lotions are well represented by the *Lotio picis carbonis*, the *Lotio plumbi acetatis* and the *Lotio plumbi cum zinco*, though it is noticeable that the *Lotio picis et plumbi* of the National Formulary does not find a place.

For the promotion of hair growth on the scalp the *Lotio stimulans* is the result of prolonged experience and the formula is:—

R Tinctura cantharidis	30 minims
Liquoris ammoniæ fortis	60 minims
Glycerini	60 minims
Aquam destillatam	to 1 ounce

If dandruff or a seborrhœic condition of the scalp calls for attention the *Lotio resorcini* is very serviceable, while the *Lotio hydrargyri et resorcini* has stood the test of time:—

R Hydrargyri perchloridi	1 grain
Resoreini	5 grains
Olei ricini	10 grains
Aleohol (60 per cent)	to 1 ounce

Mixtures

Of the mixtures, the number of which as already mentioned has risen again to 27, *Mist. alba* is as popular in the treatment of skin conditions as in most other branches of the healing art. In fact there are few diseases in which its judicious use is not beneficial. Arsenic, which at one time was regarded almost as a dermatological 'cure-all', is present in three prescriptions, the *Mistura acidi arseniosi*, the *Mistura arsenicalis alkalina*, and the *Mistura ferri arsenicalis*. Though it

is still of value in certain diseases associated with derangement of the normal process of the formation of horn cells, such as psoriasis, it is far more frequently used for its general tonic properties. The unfortunate results which may still sometimes be seen from its too prolonged ingestion have led in some cases to its too complete abandonment, but there can be no doubt that, used in moderation, it is a most valuable drug. Quinine is a remedy favoured by many in certain dermatoses, particularly lupus erythematosus and the *Mistura quiniæ acida* is a very useful variation from the plain quinine tablets. Many cases of seborrhœic dermatitis are benefited by the administration of alkalis and the following *Mistura alkalina* is a very useful prescription:—

R Sodii bicarbonatis	30 grains
Potassii bicarbonatis	25 grains
Potassii citratis	20 grains
Tincturæ cardamomi compositæ	30 minims
Aquam	to ½ ounce

For the relief of irritation, which is often such a difficult problem in dermatological treatment, the *Mistura potassii bromidi* may be valuable, though a suitable external application is usually more effective, and the bromide mixture is more useful in soothing the exhausted nervous system than in directly affecting the itching cutaneous covering. The *Mistura nucis vomicæ sedativa*, which appears in the London Hospital Pharmacopœia as the *Mist. pot. brom. co.* or 'antichlamberic mixture', is a most valuable remedy for the 'nervous depression' so common in older patients suffering from an intermittently itching condition. It is often seen at its best in cases of senile pruritus and the formula is as follows:—

R Potassii bromidi	10 grains
Tincturæ nucis vomicæ	10 minims
Spiritus ammoniæ aromatici	20 minims
Infusum gentianæ	to ½ ounce

For the treatment of rosacea, with its usually attendant gastric disturbances, there are two acid mixtures. The simple *Mistura gentianæ acida* is practically the same in all pharmacopœias, and the *Mistura acida strychninæ* is preferable in cases of lack of general tone, as follows:—

R Acidi nitro-hydrochlorici diluti ..	5 minims
Liquoris strychninæ hydrochloridi ..	2 minims
Aquam destillatam ..	to ½ ounce

The *Mistura hydrargyri perchloridi* is a mixture much favoured in the treatment of lichen planus and of necessity the *Mistura hydrargyri biniodidi*, as follows:—

R Liquoris hydrargyri perchloridi ..	30 minims
Potassii iodidi ..	5 grains
Infusum quassia ..	to ½ ounce

is invaluable in dissolving the granulomas of tertiary syphilis.

Antimony wine does not appear to enjoy the popularity it deserves and the judicious use of the *Mistura vini antimonialis* in the early or eruptive stages of many inflammatory diseases, such as psoriasis or lichen planus, will give very gratifying results. The formula:—

R Magnesii sulphatis	20 grains
Vini antimonialis	10 minims
Aquam destillatam	to ½ ounce

Salicin and sodium salicylate are both very useful in relieving the joint pains associated with certain skin diseases such as erythema nodosum, peliosis rheumatica and certain types of psoriasis and each is prescribed in a familiar mixture:—

R Salicini	15 grains
Pulveris tragacanthæ	q.s.
Aquam ehloroformi	to 1 ounce
R Sodii salicylatis	10 grains
Sodii bicarbonatis	10 grains
Aquam menthæ piperitæ	to ½ ounce

No pharmacopœia would be complete without the appearance of calcium, though it is open to grave doubt whether such a simple prescription as the following is at all an effective way of administering this drug:—

R Calci lactatis .. 20 grains
Aquam menthe piperitæ .. to 1 ounce

This is necessarily a somewhat sketchy account of the internal remedies in our Pharmacopœia, but it will emphasize the well known fact that there are really no specific internal remedies for skin diseases. The increasing modern favour for the administration of drugs by injection also has had its effect.

Pastes

Returning to the forms in which external remedies may be applied one comes first to the extremely valuable pastes. These are semi-porous applications made by the addition of a quantity of some bland absorbent powder to the ointment basis and are less irritating than ointments as the powder absorbs the discharges. Pastes may be said to combine the effects of an ointment and a powder. They should be applied to the skin either by being rubbed in or by being spread on linen or muslin and held in position by a bandage. Should they become caked over the skin, they may be removed by olive oil, and they are not suitable for use on hairy parts as they are apt to mat the hairs together or to plaster them down to the skin. The classical example is the Pasta zinci with which the name of Lassar is always associated. It is:—

R Zincii oxidi of each equal
Amyli parts to make
Adipis lanæ hydrosi
Paraffinum molle 1 ounce.

As Sir Norman Walker remarks: 'It is interesting to note that Erasmus Wilson, to whom the popularity of zinc ointment is due, used to vary the amount of zinc oxide in his prescription, and his "stiff" zinc ointment was really the pioneer of the pastes'. Any drug may be incorporated in this paste, the amount of powder being diminished if the added constituent is bulky and dry. Salicylic acid is frequently added for its softening effect on the horny layer of the epidermis, and the prescription for the Pasta acidi salicylici as it is then called becomes:—

R Acidi salicylici .. 10 grains
Zincii oxidi .. 120 grains
Amyli .. 120 grains
Paraffinum molle .. to 1 ounce

To this may be added dr. i of Liquor picis carbonis if a more anti-pruritic effect is desired. If the effect wished for is more antiseptic the Pasta monsol (15 minims monsol to the ounce of Pasta zinci) will be found most useful.

The Pasta resorcini compound is used in its three increasing strengths for its desquamating effect in the 'peeling' treatment of acne vulgaris and the prescriptions are as follows:—

R Resorcini ..	10 grains	30 grains	60 grains
Sulphuris ..	10 grains	30 grains	60 grains
præcipitata			
Zincii oxidi ..	180 minims	180 grains	120 grains
Paraffinum ..	to 1 ounce	to 1 ounce	to 1 ounce
molle.			

Pigmenta or paints are employed either as a vehicle for various drugs in a spirituous solution or as a protective coating. The Pigmentum viride is a very popular example of the former and is largely used in the treatment of superficial pus infection of the skin. It is also effective in the ringworm infection between the toes which goes by various names, such as 'athlete's foot', 'Hong Kong foot' and 'Bombay rot'. The prescription is:—

R Viridis malachiti .. 5 grains
Hydrargyri perchloridi .. 5 grains
Alcohol (60 per cent) .. 360 minims
Aquam to 1 ounce

For the combination of a drug with a protective covering the Pigmentum acidi salicylici is a good example, as follows:—

R Acidi salicylici .. 1 drachm
Collodium flexile .. to 1 ounce

The addition of 20 minims of the extract of cannabina indica makes the very familiar 'corn paint'.

Of pills very much the same may be said as of mixtures. They are of value in treating such conditions as may coexist with the skin disease and none are specifics though the Pilula hydrargyri iodidi viridis sometimes seems to affect warts like the proverbial charm and the Pilula ichthyol is said to reduce cutaneous congestion and is often employed in the treatment of rosacea when acids appear to fail.

Powders

Dusting powders are most valuable and they may be used for their protective, absorbent, astringent, anti-pruritic and antiseptic properties. They should be carefully prepared and repeatedly sifted, so that they are practically impalpable and wholly free from grit. Their protective effect is largely due to their acting as a 'dry lubricant' (like graphite in certain parts of machinery) and for this action the many talcum powders on the market are excellent. In fact the bulk manufacture of these powders is so good nowadays that individual prescribing is seldom necessary. Powders may be simply dredged on to the affected surface or if a more prolonged action is required they may be quilted into muslin bags and fixed with a bandage. For an acutely inflamed surface they have a most cooling effect as each particle helps to radiate the heat, and on an oozing or weeping surface the absorbent powders are of value in drying the skin and reducing œdema. In this latter connection starch powders are not to be recommended as the starch is liable to cake and ferment. The stearate of zinc is a better powder for this purpose. The simple Pulvis acidi borici cum zinco combines the protective and antiseptic properties very well as follows:—

R Pulveris acidi borici .. 1 part
Pulveris amyli .. 2 parts
Zincii oxidi .. 3 parts

A rather more antiseptic powder which is also mildly astringent is the Pulvis acidi salicylici compositus:—

R Acidi salicylici .. 3 parts
Pulveris amyli .. 10 parts
Pulveris talei .. 87 parts

whilst if antiseptics is the chief object the Pulvis hydrargyri subchloridi compositus may be used:—

R Hydrargyri subchloridi .. 2 parts
Pulveris acidi borici ..
Pulveris amyli .. of each 7 parts

When the astringent and anti-pruritic effect is the chief one sought the sub-gallate of bismuth, marketed under the trade name of 'dermatol', will be found very suitable.

The hopelessness of competing with the myriads of excellent soaps on the market is reflected in the fact that only three formulae are given. Far too much is made of the alkali in soap to the neglect of its other constituents. When any soap is mixed with water a certain amount of alkali is of necessity set free, and it is to that that the cleansing effect of the soap is largely due. Probably most of the irritation caused by soaps is due to the unsuitable rancid fats used in their preparation or to the perfume and dyes, and it must always be remembered that idiosyncrasy plays a large part in the irritation of soaps. 'One man's cleanliness may be another man's irritation'.

Medicated soaps sound most attractive but in practice they really have very little specific value. They do not carry the drug with them as ointments do and their dose is completely uncertain. In acne vulgaris, however, a sulphur soap is often quite useful, especially as it may be the only form of treatment that male

patients will carry out with any degree of regularity. Still, even here, the chief effect is probably due to the soap rather than its accompanying drug.

The *Solutio saponis* (equal parts of *sapo viridis* and alcohol) or scented with 15 grains of thymol ad 1 ounce is a very useful shampoo.

Ointments

Ointments are by far the most commonly used of the greasy preparations and are often most efficacious methods of acting on the skin by means of various drugs. The choice of a proper base is most important and it is of great interest to note that vaseline (*paraffinum molle*) has very largely replaced lard or benzoated lard in the latest pharmacopœia. In fact it is the base used in 33 out of the 43 formulæ given whereas in 1898 about an equal number of ointments were made up with lard and with vaseline. This is largely explained by the comparative cheapness of vaseline as well as the fact that it does not go rancid. Vaseline may prove irritating to sensitive skins when other bases may be used. It may also be combined with lanoline (*adepts lanæ*) to give greater consistence.

Ointments may be bland or protective, astringent, keratolytic, antiseptic, stimulating, or sedative. The effect will vary according as they are rubbed in, smeared on or applied thickly on linen with or without a waterproof covering. Needless to say the last method produces the most powerful effect. Simple bland or protective ointments nearly all contain zinc oxidi and may easily be rendered mildly sedative by adding 10 to 15 minims of *Liquor picis carbonis* or 1 drachm of *Liquor plumbi subacetatis fortis* as in the following:—

R. Liquoris plumbi subacetatis diluti 60 minims
Unguentum zinci to 1 ounce

The combination of mild antiseptics in a mildly sedative ointment is well exhibited in the following *Unguentum acidi borici cum eucalypti*:—

R. Acidi borici 1 grain
Olei eucalypti 10 minims
Paraffinum molle to 1 ounce

which will frequently be found to be a very 'healing ointment'. This ointment is very similar in its effect to the *Unguentum Z. E. B.* of the National Formulary.

The chief keratolytic ointments contain salicylic acid in varying strengths and may with advantage be combined with drugs of the 'reducing agent' type such as chrysarobin or mercury in the treatment of psoriasis. The *Unguentum petrol. compositum cum acid salicylic* is one of the most used formulæ for psoriasis:—

R. Liquoris picis carbonis .. 60 minims
Hydrargyri ammoniati .. 15 grains
Acidi salicylici .. 20 grains
Unguentum paraffini .. to 1 ounce

The combination of benzoic acid with salicylic acid (known the world over as Whitfield's ointment) is a powerful antiseptic as well as keratolytic and remains the best remedy for tinea infection of the glabrous skin, in spite of countless rivals of the aniline dye and other types of chemical. Whitfield's original prescription is closely followed and it is to be noted that coconut oil is included in the base:—

R. Acidi benzoici 25 grains
Acidi salicylici 15 grains
Paraffini mollis 120 grains
Olei cocois nuciferæ .. to 1 ounce

Two ointments are included which are very effective in treating seborrhœa, particularly of the scalp. The *Unguentum acidi salicylici cum sulphure* is best when there is little inflammatory reaction and its action on seborrhœic dermatitis of the body is most successful:—

R. Acidi salicylici 10 grains
Sulphuris præcipitata .. 15 grains
Adepm benzoinatum .. to 1 ounce

When there is considerable inflammatory reaction with much crusting of the scalp the *Unguentum cocois compositum* will frequently give better results:—

R. Liquor picis carbonis .. 60 minims
Sulphuris præcipitata .. 20 grains
Acidi salicylici .. 10 grains
Olei lavandulæ .. q.s.
Olei cocois nuciferæ .. to 1 ounce

The addition of 2 per cent oil of cade will add to its sedative effect.

The *Unguentum acidi carbolici cum menthol* is an excellent one for relieving irritation and the pain of ulcers, but it must always be borne in mind that the action of ointments of this type is always temporary and the irritation is very apt to return with renewed force when the first effect of the application has 'worn off'. The same comment applies to the very effective proprietary ointment known as 'percainal'. The formula of our hospital ointment is:—

R. Acidi carbolici 10 grains
Menthol 5 grains
Zinci oxidi 30 grains
Adepm benzoinatum .. to 1 ounce

Another useful anti-pruritic is the *Unguentum naphthol*, which has also the virtue of being an anti-scabies application. Its use is often very valuable in cases of papular urticaria, when the possibility of an added scabies infection may be difficult to exclude:—

R. Naphthol 22 grains
Olei sesami 360 minims
Paraffini duri 30 grains
Paraffinum molle to 1 ounce

In this summary of our 'Favourite Prescriptions' I have tried to indicate what sort of application has been found by experience to be most suitable to the different stages of skin diseases. It will be seen that many of the more modern and specialized medications, such as the various preparations of the gold salts, are not included. These medicaments are still rather *sub judice* both as to the indication for their use, their dosage and effects and it was felt the time had not yet come for their inclusion in the *Hospital Pharmacopœia*. The large firms of manufacturing chemists now put up so many of these applications in a so much more elegant form and of necessity less expensively than by the dispensing of small quantities that the art of writing elegant prescriptions is unfortunately likely to fall more and more into disuse.

Reviews

A GUIDE TO HUMAN PARASITOLOGY FOR MEDICAL PRACTITIONERS.—By D. B. Blacklock, M.D. (Edn.), D.P.H. (Lond.), D.T.M. (Liver.), and T. Southwell, D.Sc., Ph.D., A.R.C.Sc., F.Z.S., F.R.S.E. Second Edition. 1935. H. K. Lewis and Company, Limited, London. Pp. vii plus 259, with 2 coloured illustrations in the text. Price, 12s. 6d.

THE second edition of this book has appeared only four years after the first which is evidence that it has found a ready demand.

Although the original edition was kept down to the barest necessities the authors have managed to reduce it another twelve pages on this occasion by removal of non-essentials.

In the reviewer's opinion this book's chief value will be to students preparing for an examination of the standard of a Diploma of Tropical Medicine, for only the important parasites are described fully, the less important (non-pathogenic) ones being omitted or briefly described in small print. Thus for a student to use this book successfully he will need amplification of the facts given and this can only be done by a teacher during the practical classes. It is of course essential that a

properly trained student must be able to recognize with certainty all the pathogenic parasites he will encounter, but unfortunately unless he is also able to distinguish the non-pathogenic ones he may be misled into applying unnecessary or incorrect treatment to his patients.

It is admittedly extremely difficult for a student previously unacquainted with parasitology to acquire a working knowledge of all the parasites that can infect man, in the short space of an average diploma course, therefore the more experienced teachers in these subjects become the more are they inclined to reduce the amount of instruction given. The authors of this book have performed a valuable task in producing this volume of essentials, but it is doubtful if in some instances they have not perhaps gone a little too far in their efforts to make the subject easy.

Nevertheless, if the reader bears constantly in mind that the word *guide* in the title is to be taken literally he will not be disappointed.

The numerous tables and the illustrations of the life histories of many of the parasites, especially the helminths, will be found a great help in looking up and rapidly reminding one of the salient points in these often complicated cycles, and they greatly add to the value of the book.

To sum it up, this book is the best the reviewer has seen for the use of a student, when he has a teacher at his elbow ready to amplify the information it supplies, but it is not full enough for a book of reference for an isolated medical man working where parasitology is an important part of his practice.

P. A. M.

TRANSACTIONS OF THE NINTH CONGRESS HELD IN NANKING, CHINA, 2ND TO 8TH OCTOBER, 1934. (FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.)—Edited by Wu Lien-Teh, and C. Y. Wu. Volumes I and II. 1935. Published by the National Health Administration, Nanking, Republic of China. Pp. xiv plus 790 in volume I and pp. x plus 1000 in volume II. Illustrated with numerous plates, charts and tables. Price, £2 per set of two volumes

ONE of the most remarkable things about these two volumes of *Transactions* is the promptitude with which they appeared. It is usually the fate of published transactions to appear so late that everybody has entirely lost interest in them, and, if the conference is an annual one, they usually arrive just in time for the next conference; even in the case of this association where there was an interval of two years between congresses (the interval is now three), there was sometimes a very close race between the next congress and the transactions of the preceding one. China is traditionally an easy-going and fatalistic country, where to-morrow is as good as to-day and the week after next better still, but Doctors Wu Lien-Teh and Wu have belied tradition; the first volume of these *Transactions* was delivered in India within five months of the conclusion of the Congress. (We regret that we have let down this country by delaying the publication of this review, but at one time we hoped to be able to publish a short résumé of all the important papers delivered at this Congress, as we did in the case of the 7th Congress, but we had to abandon the project).

Though the *Transactions* appeared in record time, there are no signs of hurried publication in the volumes themselves. The first 80 pages are devoted to such necessary matter as lists of members, delegates, and office holders, minutes of meetings, resolutions passed, addresses of welcome from the Chinese authorities, and other speeches at the various official functions connected with the Congress. These last-named are by no means the usual formal matter, but give one an insight into the way that the Chinese government is attempting to tackle the medical problems of China. They have realized that in these days a

government is judged more on the efficiency of its medical services than on any other single branch of its administration. The addresses of H. E. President Wang Ching-wei who took a great personal interest in the Congress will be read with special interest, as also will those of that very gifted speaker H. E. Dr. J. Heng Lin, the President of the Congress. Those who have met the former at the Congress will have read with great regret that he has recently been wounded when an attempt was made on his life.

The remaining 1700 pages of the two volumes are devoted to the scientific papers and the discussions that followed their delivery. Many of these papers are important contributions to the literature of tropical medicine, and though some of them have been reprinted in other journals the majority have not, so that no medical library in the East can afford to be without these *Transactions*.

The papers are numerous and the subjects are diverse; we cannot therefore attempt to refer to them all, nor do we feel competent to single out the most important.

In a paper on dysentery in the Japanese navy, it is interesting to read that Shiga dysentery is as rare in Japan as it is in India, and that in practically all the cases that occurred, the infection was picked up in Shanghai. The majority of dysentery strains isolated were of the Flexner- and Miss-Y' groups. These of course could be subdivided into minor groups, and for epidemiological investigations it is important that they should be, but for bacteriological identification it is only necessary to use the two major group sera.

Dorothy Wong, of the Peiping Union Medical College, came to the conclusion that an agglutinating titre of 1 in 80 in a serum was sufficient evidence of the existence of dysentery at some time of life, in the case of the Flexner-Y' group, and that 1 in 40 was sufficient in the case of the Shiga organism; she found that the sera of new-born babies contained no agglutinins against *B. dysenteriae*.

Dr. Tao found that the majority of the meningococcal strains isolated in China are of group I, that is types I and III; this is very much what we have found in India; only here we appear to have found a larger number of strains that do not fall into any of the recognized groups.

The reviewer was particularly interested in a paper by Dr. Chester Frazier on the cutaneous manifestations of vitamin-A deficiency. At the Congress there were many photographs shown; these were very suggestive of the type of unhealthy skin that one sees in India; unfortunately only two of his photographs have been reproduced. The condition is very much like that described by Nicholls as phrynoderma. There seems to be little doubt regarding the specific nature of the lesions as they occur so frequently in conjunction with other recognized vitamin-A deficiency conditions.

Dr. Reiss of Shanghai has suggested the use of the serum of patients suffering from lymphogranuloma inguinale instead of the ordinary Frei's antigen for the specific test. He claims that the serum still has antigenic properties, even at the end of the fourth week of the disease.

Dr. Yushichi Minamizaki, of Tokyo, claims to have shown that hookworms can live in the intestine for a period of seven years, and independently confirm Kendrick's work in Madras.

Doctors Lily Zia and Claude Forkner's paper on acute agranulocytosis in kala-azar will be of special interest to readers in this country. Marked leucopenia is of course a well-recognized condition here, but complete agranulocytosis is a rare finding, and it is quite obvious that it does not occur with anything like the frequency that it does in China. It is accompanied by very severe constitutional symptoms and a fatal issue is common.

Worthy of special mention, and an indication of the importance of the subjects in Eastern countries, is the section on malaria which occupies about one-third of the second volume. Most of the papers in this section

are devoted to work on anti-mosquito measures and entomological studies, but there are four papers in which many of the aspects of modern treatment are discussed.

Of special interest to us in India are two papers by Lieutenant-Colonel Russell. One was on cerebro-spinal meningitis; in this he draws attention to the increase in incidence of this disease in India in the past few years. The other paper is on plague; in this he gives an account of the epidemiology of this disease from 1896 to 1933 in India, and, although plague has accounted for 12,000,000 deaths during this period, the steady decrease in the number of deaths throughout the 38 years is a fine tribute to the work of the public health authorities and sanitarians of this country.

As we have already said, it is a publication that will be of special value to all medical men in the East in whatever line of work they are engaged, but its appeal is far wider than this, and it should be in all the principal medical libraries of the world.

CLINICAL DIAGNOSIS BY LABORATORY METHODS: A WORKING MANUAL OF CLINICAL PATHOLOGY.—By J. Campbell Todd, Ph.B., M.D., and A. Hawley Sanford, A.M., M.D. Eighth Edition. Thoroughly Revised. 1935. W. B. Saunders Company, Philadelphia and London. Pp. 792, with 370 illustrations, 29 in colours. Price, 25s.

The reviewer has been familiar with the earlier editions of this book for a number of years and he has used the seventh edition as a standard book of reference in his laboratory since its publication four years ago; it will now be replaced by the present edition.

The book follows very much the ordinary lines of books on clinical laboratory methods. It begins with a very good discussion on the microscope, its theory and practical use; then follow chapters on sputum and urine examination; the latter is a very comprehensive one, covering well over a hundred pages and including a number of chemical examinations designed to test the functional activity of the kidneys; there is also some useful discussion on the clinical significance of the various findings. Chapter III, on the blood, is also a long one, but the subject has so many aspects that many of the methods have had to be described briefly, and although many alternative methods are given some had to be omitted; this is perhaps an advantage to confuse the reader less. In one of the

of the structures in the most important blood diseases is given. The blood chemistry proper, i.e., tests for the presence of blood, the determination of non-protein nitrogen, blood sugar, etc., are in a separate chapter on clinical chemistry; there is in this chapter a new diagram representing the method by which bile is formed in the liver; this will be a useful diagram for teaching purposes, when, for example, the subject is the significance of the van den Bergh tests. The next two chapters are on the gastric and duodenal contents, and the faeces, respectively. For the histamine test the rather large dose of 0.1 mgm. per 10 kilogrammes of body weight is recommended; severe reactions may follow this dose and a smaller dose will almost always be found sufficient; admittedly this fact is mentioned.

The chapter on animal parasites is very much better than are similar chapters in most books of this kind that are not written solely for the tropical worker.

There are two criticisms that we have to make. The statement made on p. 403 that free hydrochloric acid is *never absent in health* is surely not true; it is in any case contradicted on p. 413 in the statement that achylia may occur in apparently-healthy normal persons.

Certain writers have a deplorable habit of referring to workers in their own country, as originators of some method or theory, whilst ignoring much earlier work in other countries; the habit is not by any means confined to American writers but is perhaps more common amongst them. This mistaken form of

patriotism leaves an impression of either ignorance or dishonesty, and must embarrass their own countrymen, who may have been entirely innocent of any attempt to divert credit to themselves. The rapid typing method for pneumococci which is described as Sabin's (1933) is exactly the method described by Armstrong more than a year earlier. In the paper referred to, Sabin himself gave full credit to the latter worker.

However, on the whole it is a very useful book indeed and one that we can thoroughly recommend both to the clinician and the laboratory worker.

L. E. N.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY: A COMPLETE DICTIONARY OF THE TERMS USED IN MEDICINE, SURGERY, DENTISTRY, PHARMACY, CHEMISTRY, NURSING, VETERINARY SCIENCE, BIOLOGY, MEDICAL BIOGRAPHY, ETC., WITH THE PRONUNCIATION, DERIVATION AND DEFINITION.—By W. A. Newman Dorland, A.M., M.D., F.A.C.S. Seventeenth Edition, Revised and Enlarged. 1935. W. B. Saunders Company, Limited, London and Philadelphia. Pp. 1573, with 945 illustrations, including 283 portraits. Price, 30s. Plain: 32s. 6d. with Thumb Index. Flexible or Stiff Binding

To review a dictionary is not at any time an easy matter, but when the dictionary has reached its seventeenth edition, and is as well known as is Dorland's, it becomes almost impossible to do more than announce that a new edition has been published.

This dictionary appeared at the beginning of the century and the first edition contained 770 pages; in the present edition there are 1573 pages. The prospect for future generations of medical men is an appalling one, but the importance of the possession of a sound medical dictionary to every medical student, under- or post-graduate, if he is not to be frequently puzzled by words in books and scientific journals, is manifest.

One of the features of this dictionary is the number of thumb-nail illustrations in the text. These are often very helpful. They include so many photographs of eminent medical men of the past that the words 'and biography' might reasonably have been added to the title.

We have kept this dictionary on our table for about a month and have referred to it very frequently, particularly with reference to tropical diseases, and so far we have not found any of the mistakes that often find their way into American medical dictionaries (incidentally all medical dictionaries are American). We did, however, find one mistake; lymphogranuloma inguinale is not the same as ulcerating granuloma of the pudenda, as the dictionary states, though in the next paragraph the former condition is correctly described under the unusual name, lymphogranulomatosis inguinalis.

A large number of posological and other tables are included, either in their appropriate places or at the end of the book, and as well as the text illustrations there are numerous useful full-page plates, some of which are in colour. Altogether it is a dictionary that we can thoroughly recommend.

L. E. N.

FORENSIC CHEMISTRY AND SCIENTIFIC CRIMINAL INVESTIGATION.—By A. Lucas, O.B.E., F.I.C. Third Edition. 1935. Edward Arnold and Company, London. Pp. 376. Price, 18s.

The book is an example of the fact that a large scope is not always inseparable from a large bulk. The 376 pages, including the preface, the introduction and the index, give an excellent insight into the scope of chemistry and scientific methods in general (which '... there is no doubt that the chemist, by reason of his training and experience in manipulation and his skill in testing and in general laboratory practice, is well qualified to understand....') in detecting crime. In view of the diversity of the items discussed (blood-stains; clothing; counterfeit coins; documents; dust,

dirt, glass fragments, stains and marks; explosives and explosions; fibres, woven fabrics, string and rope; finger prints, footprints and tracks of vehicles; fires and insurance frauds; firearms, cartridges and projectiles; microscopy, photography, x-rays, ultra-violet rays and infra-red rays; poisons; preservation of the human body after death; robbery from letters and parcels; and tobacco) a full treatment of items other than documents and firearms, etc., cannot be claimed. The list of references which is full and discriminately selected, however, will put the seeker on the path.

Some descriptions of techniques and findings are rather condensed, yet, speaking strictly, cannot be called obscure. Graphic aids would have made them easier to follow, for instance, tabular ensembles of serological procedures, photomicrographs of haemin crystals and of appearances characteristic of iso-agglutination, photographs (with enlargements) of the faults which characterize counterfeit coins and forged documents, and illustrations of the spectrum with various bands.

It is noted that in the search for blood-stains, while ultra-violet and infra-red rays have been requisitioned, the simple expedient of a candle light in a dark room, for dark fabric, has not been mentioned.

With the introduction most medico-legal workers may not agree. Details concerning record and custody of the exhibits may not 'possibly' appear, but may really be 'trivial and unnecessary'. In India medico-legal workers deal every year satisfactorily with tens of thousands of exhibits from thousands of cases without special attention to the sizes of note books and pencils they use, without sealing locked rooms and cupboards, and without any strain on the imagination. Again, forensic medicine appears to most of us to include chemistry with justification.

The paper, the printing, the binding and the size are good. Only one printer's error on page 101 arrests attention.

The book deserves a place on the desks of medico-legal workers, handwriting experts, censors, lawyers and policemen.

S. D. S. G.

INJURY AND INCAPACITY WITH SPECIAL REFERENCE TO INDUSTRIAL INSURANCE.—By H. E. Griffiths, M.S. (Lond.), F.R.C.S. 1935. Baillière, Tindall and Cox, London. Pp. viii plus 270. Price, 12s. 6d. Obtainable also from Jordan and Sons, Limited, 116, Chancery Lane, W.C. 2, London

THIS book is based on an analysis of 50,000 consecutive cases of accidents in the records of one of the largest English insurance companies dealing mainly with claims arising out of the Workmen's Compensation Acts. If the reader however assumes that he will, on that account, be faced by a mass of tabulated statistics, he will be pleasantly disappointed. Statistics are included, but skilfully whittled down to practical essentials and presented in such form as to be available for easy comparative reference in almost any individual case of incapacity. On a bare and unobtrusive statistical framework the author has succeeded in conveying considerable professional information and while the presentation is normally from the view-point of the compensation acts there is much of value to the ordinary medical man concerned only with diagnosis and prognosis, apart from the question of incapacity in its relation to compensation.

The Workmen's Compensation Act, 1923, has been in force in this country for 12 years. The appearance of this book is timely for while it cannot be said that the 'compensation complex' has yet seriously affected labour in India it is probable that it will not be long before the cost to industry of the Indian Act will be very considerable. The average practitioner, and to a greater degree the official worker, will find it difficult to escape contact with cases coming under the act. To them this book will serve as a valuable source of comparative figures in arriving at an opinion on any

given case. Industrial surgeons working for commercial bodies who have to appear before commissioners under the act as witnesses will do well to be acquainted with it as lawyers will discover in it a sound guide on medical problems with which to confound the unwary.

A special feature is a series of 60 tables. These give to a decimal place the average ascertained periods of incapacity in weeks for workers of different age groups for 60 different type accidents. A peculiar interest attaches to them apart from their intrinsic value. With increasing knowledge of them it is possible that determined malingerers will resist a return to work, whatever their condition, in less than the times given. On the other hand closely supervised and efficient medical organizations should find reasons in them for making every effort to see that their own periods of incapacity do not fall short of those given here without good reason. These are the first published figures from a reliable source which afford a standard for comparison and are therefore of real value to all interested in reducing the cost to industry of the upkeep of its 'wounded'. For obvious reasons the identity of the insurance company has been kept a secret.

The book contains detailed descriptions of 24 physical types of workers setting out minimal physical requirements in each type. An alphabetical list of 1,500 occupations at the end of the book is classified according to these types so that the general assessments in the 50 tables referred to above can be modified to any individual case with very little trouble.

The book is obviously the result of considerable labour and the material has been presented in a clear and original manner. Nothing like it has previously appeared in book form in England and it can be recommended to all those who have to deal with the Compensation Act, whether lawyers or doctors, as well as laymen concerned with the economical employment of labour. The price is reasonable and the volume commendably light and handy.

H. R. R.

THEORY AND PRACTICE OF ANÆSTHESIA.—By M. D. Nosworthy, M.A., M.D., B.Ch. (Cantab.). 1935. Hutchinson and Company (Publishers), Limited, London. Pp. 223, with 35 illustrations. Price, 12s. 6d.

THAT the science of anæsthesia is making a rapid advance is borne out by the fact that a large number of new anæsthetic drugs are being introduced every year. This small treatise on the theory and practice of anæsthesia is the outcome of the vast experience of the author in the field of anæsthesia, not only as anæsthetist to a large hospital but as a teacher. This has enabled the author to study the difficulties of those who are new to the work regarding the induction of various forms of anæsthesia, the complications arising during the induction stage and the management of post-anæsthetic complications.

The author discusses fully the time-honoured chloroform and ether anæsthesia and then deals with all the modern methods of anæsthesia keeping in view all the recent drugs introduced for the purpose. The chapters on shock, pre-medication, regional and spinal anæsthesia deserve special mention. The incorporation of references at the end of chapters is useful.

The book though primarily intended for beginners can be confidently recommended even to the general practitioner for his ready reference in daily practice. It is well printed and contains many useful illustrations.

R. N. C.

OPHTHALMIC NURSING.—By M. H. Whiting, O.B.E., M.A., M.B., B.Ch. (Cantab.), F.R.C.S. Second Edition. 1935. J. and A. Churchill, Limited, London. Pp. xiv plus 191, with 54 illustrations. Price, 5s.

THIS is the second edition of this book which is based on the practices carried out at Moorfields Eye

Hospital, London, on the result of more than a century of experience and tradition.

It consists of fourteen chapters in which are described in a simple and concise manner the anatomy and physiology of the eye, the micro-organisms and their relation to disease, the examination of the eye, diseases of the eye, ophthalmic therapeutics, methods of treatment, operations, nursing of operation and non-operation cases, and eye nursing in schools.

During recent years many important advances have been made in ophthalmology such as the treatment of retinal detachment, orthoptic training in the treatment of squint cases, the use of ultra-violet-light therapy and diathermy. These have necessitated the addition of a new section in the second edition.

In India eye diseases are more prevalent than in other countries and so a knowledge of the nursing of ophthalmic cases is of great importance. Many nurses unfortunately are inadequately trained in ophthalmic nursing and many pass through their course without any at all.

The book is an admirable one and is well illustrated with excellent diagrams. It will be found most valuable not only to nurses but to house surgeons and general practitioners.

We have great pleasure in highly recommending it as a book that should be kept in every hospital in India.

E. O'G. K.

THE ESSENTIALS OF LIGHT TREATMENT.—By K. M. Anderson, M.D., B.S. (Durham). 1935. Haldimore, Tudall and Cox, London. Pp. ix plus 84. Price, 8s.

This small book is written for the use of massenists by a medical practitioner who has lectured to massage students.

The seven chapters in the book are each in the form of a lecture and are remarkably clearly written. According to the title the author sets out to give the essentials of light treatment and she has certainly succeeded. In addition to the massage practitioners for whom it has been written it might profitably be read by medical men in general practice who know nothing of this fairly new and important form of therapy, because in it they will learn the types of cases that can be sent for ultra-violet-ray treatment with prospect of benefit. And still more important is the second-last chapter which is devoted to the contraindications, dangers and overdosage with light rays.

Abstracts from Reports

REPORT ON THE WORKING OF THE PUNJAB MENTAL HOSPITAL, LAHORE, FOR THE YEAR 1934

The total number of patients, i.e., 1,459, treated during 1934 was only a little less than the abnormal number of last year; and again a number of patients had to be refused admission, owing to lack of accommodation. It is hoped that, with the improvement in the financial situation, it will be possible before long to take up again the question of an extension of the hospital buildings. The number of patients discharged as cured was considerably less than in the previous year, viz, 128, as compared with 175. As many as 67 'not improved' cases were discharged, and a considerable number of incurable patients were handed over to their relatives, to facilitate the admission of curable cases.

The health statistics show an improvement even on the eminently satisfactory record of last year, the death rate of 6.19 being again the best on record. Pneumonia, pleurisy and tuberculosis as usual accounted for a considerable proportion of the 68 deaths. A noteworthy feature is the mortality (7) due to ankylostomiasis. The prevalence of this disease, particularly in sub-montane areas, has only been realized in recent years, and an intensive campaign is being waged against it in Gurdaspur district. The chief features of this insidious disease are the gradual deterioration, both physical and mental, of the sufferer, and the difficulty in detection; and the number of deaths from it at the Mental Hospital is significantly illustrative of its nature. The figures for deaths by violence are less disquieting than in recent years, being one death by suicide and one by accident. The staff was recently increased, and further increases are under contemplation; and it is confidently expected that, as a result of this and of special arrangements for exceptionally dangerous patients, there will not be a recrudescence of homicidal cases.

The figures showing the net cost of the institution are necessarily misleading, for various reasons. Thus the net cost in 1933 was only Rs. 43,704, owing to an income of Rs. 2,35,092 as against gross expenditure of Rs. 2,78,796, whereas the net cost for 1934 is Rs. 1,17,298, the recoveries having been only Rs. 1,58,998 as against gross expenditure of Rs. 2,76,296. These variations are due to difficulties in recovering payments from local bodies and other administrations. For example, a sum of Rs. 35,000 on account of military patients has been in dispute for many years with the Military Department, and it is hoped that the amount

encouraged to settle in the smaller towns. Government have been recommended to subsidize twenty doctors, as an experiment, for three years on condition that they settle in selected villages and treat poor people free of cost. This important experiment has been favourably considered by Government, and it is hoped that sanction will be accorded.

It is gratifying to note that there is a continuous increase in the number of patients treated in Government hospitals. The total number of patients treated during the year in all the hospitals and dispensaries, including jail hospitals, was 2,167,612 against 1,864,262 in the previous year showing an increase of 303,350.

The total attendance in all the medical institutions of the Dominions has increased by 66.8 per cent in the past five years. This is not the result of any increase in sickness but is the measure of public confidence gained by medical officers now efficiently supplied with drugs and appliances.

Maternity work.—The number of maternity cases attended to in the various hospitals and dispensaries was 3,341 compared with 2,426 in the year before.

Plague.—As in previous epidemics the spread of infection was entirely due to human migration. This was chiefly effected by:—

1. Introducing actual cases of plague.
2. Introduction of infected bedding and clothing.
3. Entertaining relatives or friends from infected areas.
4. Visiting the sick.

The spread of infection when infection is once brought to a non-infected locality depends on rats. In Hyderabad the rat population, owing to the continuous anti-rat campaign, had been so reduced that the spread of infection was slow. The temperature, the humidity of the air and other factors beyond our control were all favourable for a widespread epidemic of plague, but for this intensive rat destruction throughout the year the plague epidemic would have been more severe, and its spread from locality to locality more rapid.

The spread of plague formerly was much encouraged by concealment of rat-falls and plague cases. Such concealment is now uncommon and the public is co-operating to an increasing extent with the Plague Department. Though no legal action was taken under the recently sanctioned plague rules, yet their very existence helped the department in persuading recalcitrants to follow the right course.

Health camps.—In Hyderabad the Government has spent an enormous amount in providing accommodation for the people during plague epidemics. There are at present 14 permanent camps containing 1,935 sheds and capable of accommodating 16,695 persons. During the fourteenth epidemic besides these permanent camps three temporary camps were opened. The permanent sheds were extended as the occasion demanded and temporary huts were added to permanent camps; 1,486 temporary huts were provided capable of accommodating 4,458 persons.

Malaria.—Returns from different selected hospitals and dispensaries in Hyderabad City show reduction in the malaria attendance from 47 per cent of total attendance before the campaign commenced to 13 per cent during the present year. The steady decrease in the incidence of malaria since the commencement of the antimalarial campaign is marked and is due to anti-larval measures; further improvement may be confidently expected with the closing of wells and improvement in surface drains. Anopheline mosquitoes breeding in the wells, which are not treated or irregularly treated for want of permission, are capable of maintaining the infection in the city in the presence of a large number of people, particularly children, with gametocytes in their blood from former attacks of malaria. It is probable that many cases of malaria seen in the dispensaries are relapses of old infections and not new infections. The splenic index has fallen appreciably during the last four years.

Vaccination.—The total number of vaccinations performed during the year was 205,916 compared with 173,960 the previous year.

The cost of vaccinations which was met by the Local Fund Department and the Hyderabad Municipality aggregated Rs. 61,252-9-0 against Rs. 56,199-9-3 last year. The average cost of each successful vaccination was five annas one pie against five annas eleven pies in the preceding year.

Infant welfare centres.—A second infant welfare centre was opened during the year. The Hyderabad Municipality sanctioned funds for this centre in addition to the Darulshafa centre in the city area, both under the control of the Director of the Medical Department. The Director is assisted by a ladies committee consisting of a president and six members including a secretary.

The activities of the two Hyderabad centres during the year of report were briefly as follows:—

The infant welfare centre work falls into three classes:—

- (1) Before the child is born ante-natal work to prevent complications.
- (2) The provisions of reasonably skilled and clean attendance at the time of childbirth and afterwards so that infection may be prevented.
- (3) Assisting the mother in rearing children in a healthy way and preventing the onset of disease.
- (4) Domiciliary visits to the new-born.
- (5) Training and registering of dais.

It is impossible to abstract fully this voluminous report which, including tables, covers 318 pages. The few salient features we have chosen will show, however, that public health in Hyderabad State is receiving much attention and that education of the public is proceeding along with the extension of health regulations with very satisfactory results.]

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER, CITY OF BOMBAY, FOR THE YEAR 1934

Despite a small increase in the total mortality, the health conditions of the city during the year under report were satisfactory. There was no epidemic during the year. The number of live births registered during the year was more by 6,351 than the number of deaths that took place in the city. This excess of births over deaths was equivalent to 5.4 per 1,000 population calculated on the census of 1931. Before 1931 there was no such excess since 1866, the year in which birth records were instituted.

The number of live births registered was 33,724 being 2,798 more than in 1933, 9,275 more than the average of the last ten years 1924 to 1933 and the highest on record since 1866. The birth rate calculated on the census population of 1931 was 29.0 births per 1,000.

The total number of deaths from all causes was 27,370 being 196 more than in 1933, 1,522 more than the average for the last five years (1929 to 1933) and 1,322 less than that for the preceding decennium (1924 to 1933). The death rate or the number of deaths in the year per 1,000 of the census population of 1931 was 23.6 as against 23.4 in 1933 and 23.0 the rate recorded for the decennium 1924 to 1933.

Plague was reported as the cause of 31 deaths during the year as against 48 in 1933 and 127 the average of the last ten years 1924 to 1933.

Smallpox caused 152 deaths as against 2,659 in 1933 and 955, the average for the last decennium 1924 to 1933.

Cholera was registered as the cause of 13 deaths being 4 less than in 1933 and 19 less than the average for the ten years 1924 to 1933.

Influenza was prevalent in a mild form in the city during the year and caused 98 deaths as against 76 in the preceding year and 68 the average for the last decennium 1924 to 1933.

The deaths from diseases of the respiratory system numbered 10,056 being 954 more than in 1933 and 405 less than the average of the last ten years 1924 to 1933.

Tuberculosis accounted for 1,856 deaths as against 1,594 in 1933 and 1,576 the average for the preceding decennium 1924 to 1933.

One hundred and one deaths were due to malaria, being 30 more than in 1933 and 201 less than the average of the last decennium (1924 to 1933). There were 1,397 deaths from ague and remittent fever as against 1,192 in 1933. The average number of deaths for the last ten years (1924 to 1933) from malaria was 305 and from ague and remittent fever 1,697.

The deaths among infants under one year of age numbered 8,253 against 8,320 in 1933 and 7,564 the average for the last ten years (1924 to 1933). The rate of infant deaths per 1,000 births registered was 245.

Compared with the decennial averages (1924 to 1933) the total number of deaths shows a decrease of 1,322, the principal decrease in the mortality being 19 deaths under cholera, 96 under plague, 803 under smallpox, 204 under malaria, 300 under ague and remittent fever, 836 under diarrhoea, enteritis and dysentery and 405 under diseases of the respiratory system. On the other hand there was an increase of 46 deaths under measles, 30 under influenza, 68 under enteric fever, and 280 under tuberculosis.

[The above summary shows that the acute infectious diseases are being successfully controlled and to some extent overcome, but the increase in deaths from tuberculosis should be a matter of great concern to the municipal authorities.]

ANNUAL REPORT OF THE MALARIA ADVISORY BOARD, FEDERATED MALAY STATES, KUALA LUMPUR, FOR THE YEAR 1934. By A. NEAVE KINGSBURY, CHAIRMAN

THIS report does not lead itself to abstraction nor are the records of the work of this board likely to interest the majority of our readers, nevertheless it is of value as a demonstration of the importance of co-operation between all sections of a community in attacking the many problems of malaria control. It should be read in the original by all malaria control officers.

Correspondence

INTRA-UTERINE MALARIAL INFECTION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to our report on the use of atebirin in malaria sent to you for publication in the *Indian Medical Gazette*, we would like to report an interesting case recently treated, details of which we annex below.

A lady in an out-station in her seventh month of pregnancy had several attacks of malaria and was treated by the local doctor. She had about eighteen attacks of fever and in desperation was brought to this town for treatment by us with atebirin, as nothing seemed to do her good. She was promptly given two injections of atebirin dihydrochloride on two successive days. She had no fever after the second injection, but was given oral treatment of two atebirin tablets daily for five days. She remained free of fever even during her puerperium, which took place at term.

The child was a weakling and weighed five pounds at birth. When the infant was twelve days old she developed a temperature which recurred on the thirteenth and fourteenth days. One of us was then sent for and took a blood film in which we found a heavy malarial infection—mixed benign and malignant tertian; benign tertian gametocytes were present. While the film was being examined a message was

received that the child was sinking and that it would not be necessary for the doctor to go back to give the child an injection. On arrival there we found the child in a very low condition with bluish lips, and more or less unconscious and unable to swallow. The pulse was feeble and very rapid. After stimulation with camphor and ether, an injection of atebirin dihydrochloride—half tablet—was given. The next morning the child seemed much better, was taking the breast and was more lively. A second injection of the same strength was given and the temperature dropped to below normal and the improvement was maintained. This was followed by per-oral treatment with atebirin and quinine powders, and to-day the child is putting on weight and gaining strength, and is quite lively. The infection in this case must have been through the maternal blood, while the child was *in utero*.

Yours, etc.,

A. E. SPAAR, F.R.C.S.E.

KANDY,
15th October, 1935.

EPIDEMIC DROPSY

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I shall be very much obliged if you will kindly enlighten me on the following points. The September issue of the *Indian Medical Gazette* contains a number of articles on 'Epidemic Dropsy'—the burning question of the day—even in the remotest villages.

The treatment indicated is tincture ephedra vulgaris for the heart, which is analogous to the action of adrenalin and so will accelerate the heart. What should be done in the following case of epidemic dropsy?

- (1) Patient, aged 7 years; history of beri-beri—three months.
- (2) Sudden dilatation of the heart—apex beat diffuse and 1 inch lateral to the nipple line.
- (3) Pulse 170 and respiration 70 per minute.
- (4) Haemoglobin—45 per cent. The patient suffering extremely from dyspnoea—apparently cardiac in origin.
- (5) Temperature—101°F.

Questions

- (1) Whether tincture ephedra should be given or not—if so in what dose?
- (2) Whether digitalin, cardiazol, adrenalin (accelerator) should be given in such cases?
- (3) What about giving 'coramine'?
- (4) If digitalin, digifortis, digistan (B. C. P. W.) produce no action, what is to be done?
- (5) Whether blood letting should be done in anæmic cases like this?
- (6) Is Vitys (B. C. P. W.) to be given?

I shall be very much obliged if you will kindly give me detailed advice on these points.

Yours, etc.,

S. P. ROY CHAUDHURY, M.B. (Cal.).

PALANG,
24th September, 1935.

[Note.—Sudden dilatation of the heart after an attack of epidemic dropsy for three months is obviously a grave condition. Such an advanced case with organic cardiac changes should be treated as one of acute cardiac failure. Blood letting should be done when there are indications of great distension of the right chambers of the heart—as, for example, severe dyspnoea, cyanosis, engorgement of the veins of the neck and weak pulse. If venesection be not possible, application of leeches in the liver region is a good substitute. With a pulse rate of 170 it is advisable to give strophanthin gr. 1/500 intravenously followed by oral administration of digitalis or pandigital, although they are not so effective in these cases as in acute failure due to mitral valvular disease, e.g., auricular fibrillation. Cardiazol or camphor in ether and glucose are given also. Coramine can be tried, but it is more useful in cardio-respiratory

failure due to anaesthesia or poisoning. If the blood pressure be low—tincture ephedra (up v to m x, t.d.s., in a boy of 7 years) will help the process of circulation by counteracting the dilatation of capillaries that occurs even in the heart of epidemic dropsy cases.—*Enron, I. M. G.J*

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL R. N. CHOPRA, C.I.E., Professor of Pharmacology and Officiating Director, School of Tropical Medicine, Calcutta, is appointed to officiate as Surgeon-General with the Government of Bengal, with effect from the 13th September, 1935, *vice* Major-General D. P. Goil, granted leave.

Lieutenant-Colonel J. Rodger, M.C., Civil Surgeon, Sibi and Loralai, is appointed to officiate as Residency Surgeon and Chief Medical Officer in Baluchistan, in addition to his own duties, with effect from the forenoon of the 14th September, 1935, and until further orders.

The services of Lieutenant-Colonel F. A. Barker, O.B.E., Officer on special duty in the Home Department, are replaced at the disposal of the Government of the Punjab, with effect from the 16th September, 1935.

Lieutenant-Colonel T. C. Boyd, on return from leave, is reappointed as Principal, Medical College, and Superintendent, Medical College Hospitals, Calcutta.

Lieutenant-Colonel B. H. Singh, Officiating Principal, Medical College, and Superintendent, Medical College Hospitals, Calcutta, on relief, is posted to Burdwan as Civil Surgeon, *vice* Rai Dr. J. N. Chatterji Bahadur.

Lieutenant-Colonel T. J. Anderson, on return from leave, is reappointed as Professor of Clinical Surgery, Medical College, Calcutta.

Lieutenant-Colonel P. F. Gow, on return from leave, is reappointed as Professor of Midwifery, Medical College, Calcutta.

Major A. D. Loganadan is appointed as Officer on special duty in the office of the Public Health Commissioner with the Government of India, with effect from the 9th September, 1935.

Major J. C. Drummond, Officiating Professor of Clinical Surgery, Medical College, Calcutta, on relief, is appointed as Civil Surgeon, Hooghly, *vice* Lieutenant-Colonel C. A. Godson.

Captain C. L. Parichha, who was provisionally appointed Professor of Pathology and Bacteriology, School of Tropical Medicine, Calcutta, is confirmed in the appointment, with effect from 15th July, 1933.

Captain A. M. Sheridan is confirmed in civil employment under the Government of India, Department of Education, Health and Lands, with effect from the 1st September, 1935.

The probationary appointment of the undermentioned officer is confirmed:—

Captain G. P. Charlewood. Dated 28th September, 1935.

Captain F. H. A. L. Davidson made over executive charge of the Rajshahi Central Jail to Mr. Chas. A. W. Luke on the forenoon of the 1st October, 1935.

The services of Captain H. S. Waters are placed at the disposal of the Chief Commissioner, Delhi, for appointment as Civil Surgeon, New Delhi, with effect from the 16th October, 1935.

TEMPORARY COMMISSIONS

To be Lieutenants

Bashier Hussain Sayed. Dated 17th June, 1935.

V. Sivasankaran. Dated 22nd June, 1935.

Jagdish Ram Vaid. Dated 24th June, 1935.

Kamarasu Narasimha Rao. Dated 1st July, 1935.

Bhagwan Singh Khurana. Dated 1st July, 1935.

PROMOTIONS

Colonel to be Major-General

E. W. C. Bradfield, C.I.E., O.B.E., V.H.S. Dated 14th August, 1935.

Lieutenant-Colonel to be Colonel

N. S. Sodhi, M.C. Dated 12th August, 1935.

Majors to be Lieutenant-Colonels

S. Nag. Dated 10th September, 1935.

J. Rodger, M.C. Dated 18th September, 1935.

G. B. Hanna. Dated 30th September, 1935.

RETIREMENTS

Major-General Sir R. McCarrison, Kt., C.I.E., K.H.F. Dated 19th August, 1935.

Major-General H. R. Nutt, K.H.S. Dated 14th August, 1935.

Colonel A. H. Proctor, D.S.O. Dated 21st August, 1935.

RELINQUISHMENTS

Temporary Commissions

Dated 31st August, 1935

Captain A. M. Khan.

Captain P. P. Chowdry.

Dated 1st September, 1935

Captain H. K. Handoo.

Captain P. N. Sathe.

Dated 5th September, 1935

Captain D. N. Basu.

Dated 8th September, 1935

Captain H. S. Ahluwalia.

RESIGNATION

Captain J. M. Mathew resigns his commission, 5th September, 1935.

Notes

INTRATRACHEAL INSUFFLATION APPARATUS

Messrs. Down Brothers of London have made for us the apparatus necessary for intratracheal insufflation of an oxygen-carbon-dioxide mixture in the treatment of asphyxia neonatorum, as described in the *Lancet* of 30th March, 1935.

The direct vision pharyngoscope illustrated is a modification of Howarth's Chevalier Jackson's instrument which has been designed for use in the new-born infant. The speculum is 10 cm. long and its greatest outside diameter is 1.6 cm. The spatula is very short so that the soft palate does not obstruct the line of vision. The handle of the instrument is parallel to the speculum and joined to it by a shank 11 cm. long. This parallel handle gives better control than one set at a right angle to the speculum, and a shank of this length gives sufficient clearance between the handle and the chest wall during use. A wide infra-lateral slot runs the entire length of the speculum so that the pharyngoscope can easily be withdrawn without displacing the catheter when the latter has been introduced into the trachea. The illumination is by a lamp situated at the distal end, and the current is supplied by a battery enclosed in a separate wooden box with a variable resistance. In practice this arrangement of having a large separate battery has been found to be very satisfactory, since a dry-cell purchased eighteen months ago is still in use.

The catheter used is a Magill's silk-web endo-tracheal catheter with a funnel-shaped end. Sizes 3, 4 and 5 give a suitable range. The choice between these sizes is determined by the size of the infant.

The apparatus for delivering the oxygen-carbon-dioxide mixture (90 to 95 per cent oxygen and 5 to 10 per cent carbon dioxide) consists of a rubber bag of 3,000 c.c. capacity, fitted at one pole with an inlet tube

which can be connected to the supply of gas, and through which the bag can be filled. A tap on the inlet tube allows the bag to be disconnected from the supply of gas, if necessary, so that it can be kept in readiness

in a convenient place, after having been filled. At the opposite pole of the bag is the outlet tube also furnished with a tap. This rubber tube is about 2 feet long and terminates in a conical glass connection which is easily connected to the funnel-shaped end of the endo-tracheal catheter after the latter has been introduced through the direct vision pharyngoscope. By means of a metal T-piece, an aneroid manometer is attached to the outlet tube near its exit from the bag. This manometer has been specially made to register pressures within a range from 0 to 50 cm. of water.

The whole apparatus is compact and can be easily carried in the midwifery bag. By compressing the bag with the hand the gas can be forced through the endo-tracheal catheter at any desired pressure, and any variations in pressure are immediately recorded on the manometer. The pressure required in the bag is usually 30 to 35 cm. of water, and this is sufficient to produce a pressure of about 10 cm. of water in the lungs themselves, provided a suitable size of catheter is chosen depending upon the size of the infant. If necessary the bag can be continually refilled without interrupting the process of sufflation.

T. C. P. ANTISEPTIC

SAMPLES of T. C. P. (Trichlorophenylmethyl-iodo-licyl) were sent to the Clinical Research Association

Limited, London, for testing; an extract from the report is given below:—

Test for the determination of bactericidal action of T. C. P. in the presence of blood serum

In T. C. P. to which 20 per cent blood serum has been added the *Staphylococcus aureus* was killed in 30 seconds.

Similar results were obtained with the undiluted T. C. P. solution.

Test to determine penetration power of T. C. P.

Staphylococcus aureus was again used, the control plate being submitted to 1 per cent phenol solution as against a 1 per cent solution of T. C. P. The following results were obtained:—

1 per cent phenol solution—practically no penetration.

1 per cent T. C. P. solution—marked penetration ring.

Test to determine non-destruction of tissue cells by T. C. P.

Pus leucocytes were submitted to the action of T. C. P. for a period of 5 minutes. They were then washed and examined, stained and unstained. Controls with leucocytes from the same specimens were similarly examined.

In comparing the treated and untreated leucocytes it is noted that no injury to the unstained cell structure is apparent.

In the stained films the treated cells, in some instances, showed slight shrinkage, and the differentiation between nucleus and protoplasm was not quite so clear cut, but, in view of the observation on unstained specimens, this cannot be regarded as definite evidence of injury to the cell tissue, as it may be something in the nature of an altered staining reaction.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
